Associate Editors

Paulette M. Gillig  
Professor of Psychiatry and Director of Rural Psychiatry Division  
Department of Psychiatry  
Wright State University Boonshoft School of Medicine  
Dayton, OH  
USA

Eric R. Kandel  
University Professor, Neuroscience, Psychiatry, Physiology and Cellular Biophysics, Biochemistry and Molecular Physics  
Fred Kavli Professor and Director, Kavli Institute for Brain Science  
Senior Investigator, Howard Hughes Medical Institute  
Columbia University College of Physicians and Surgeons  
New York, NY  
USA

David A. Mrazek  
Professor of Psychiatry  
Department of Psychiatry and Psychology  
Mayo Clinic  
Rochester, MN  
USA

H. Jonathan Polan  
Adjunct Associate Professor of Clinical Psychiatry  
Department of Psychiatry  
Columbia University College of Physicians and Surgeons  
New York, NY  
USA

Michelle B. Riba  
Clinical Professor  
Department of Psychiatry  
University of Michigan  
Ann Arbor, MI  
USA

Steven P. Roose  
Professor of Clinical Psychiatry  
Department of Psychiatry  
Columbia University College of Physicians and Surgeons  
New York, NY  
USA

Bruce J. Rounsaville  
Professor of Psychiatry  
Director of Research, Division of Substance Abuse  
Department of Psychiatry  
Yale University  
New Haven, CT  
Director, Veterans’ Affairs Connecticut Healthcare Center  
West Haven, CT  
USA

Andrew E. Skodol  
Professor of Clinical Psychiatry  
Department of Psychiatry  
Columbia University College of Physicians and Surgeons  
New York, NY  
USA

William H. Sledge  
George D. and Esther S. Gross Professor of Psychiatry  
Department of Psychiatry  
Yale University  
Medical Director, Yale-New Haven Psychiatric Hospital  
New Haven, CT  
USA

Robert J. Ursano  
Professor of Psychiatry and Neuroscience  
Center for Traumatic Stress  
Chair, Department of Psychiatry  
Uniformed Services University of the Health Sciences  
Bethesda, MD  
USA

Assistant Editor

Melissa Arbuckle  
Assistant Professor of Clinical Psychiatry  
Department of Psychiatry  
Columbia University College of Physicians and Surgeons  
New York, NY  
USA
Dedications

With love and thanks to Cathy, Joshua, David and Sarah and to my parents, Goodie and Zelda, for your love and support.

Allan

To my wife Rena, to my children Sarah, Rachel and Jonathan, and to my mother Miriam, for their enduring love and support.

Jerry

To my father Howard (RIP) and mother Ruth who inspired me; and to my wife Rosemarie and sons Jonathan and Jeremy who supported me then and now.

Jeffrey

To my wife, Leslee, and my parents, David and Reda, for all of your love and support.

Michael

To my wife Piera, my son Federico and my parents Federico and Olga for their love and support.

Mario
Contents

Color plates appear between pages 244 and 245 and between pages 2356 and 2357

Volume 1

List of Contributors xxxi
Preface to this Edition xxxix
Preface to the First Edition xli
Preface to the Second Edition xlii

Section I Approaches to the Patient 1
Section Editor: Robert J. Ursano

Chapter 1 Listening to the Patient 3
Paul C. Mohl

Listening: The Key Skill in Psychiatry 3
The Primary Tools: Words, Analogies, Metaphors, Similes, and Symbols 4
How Does One Hear Words in This Way? 5
Listening as More Than Hearing 5
Common Blocks to Effective Listening 6
Crucial Attitudes That Enable Effective Listening 8
Theoretical Perspectives on Listening 10
Using Oneself in Listening 11
To Be Found: The Psychological Product of Being Heard 12
Listening to Oneself to Listen Better 13
Listening in Special Clinical Situations 15
Growing and Maturing as a Listener 16

Chapter 2 Physician–Patient Relationship 20
Amy M. Ursano, Stephen M. Sonnenberg, Robert J. Ursano

The Placebo Effect 20
Roles and Motivations 21
Modern Medicine and the Physician–Patient Relationship 21

Chapter 3 The Psychiatric Interview: Settings and Techniques 33
Edward K. Silberman, Kenneth Certa, Abigail Kay

Goals of the Psychiatric Interview 33
The Psychiatric Database 37
Conduct of the Interview 41
Special Problems in Interviewing 47

Chapter 4 The Cultural Context of Clinical Assessment 54
Laurence J. Kirmayer, Cécile Rousseau, G. Eric Jarvis, Jaswant Guzder

Introduction: The Cultural Matrix of Psychiatry 54
What is Culture? 54
Culture and Gender 56
The Cultural Formulation 57
Cultural Competence 60
Conclusion: The Limits of Culture 64

Chapter 5 Professional Ethics and Boundaries 67
Richard S. Epstein, Ahmed Okasha

Introduction 67
Ethical Behavior and Its Relationship to the Professional Attitude 67
The Coherent Treatment Frame and the Role of Therapeutic Boundaries in Effective Psychiatric Treatment 71
Boundary Violations 71
Components of the Coherent Psychiatric Frame 73
Summary 78
Chapter 6 Legal Issues in Psychiatric Practice 81
David M. Benedek, Thomas A. Grieger
Introduction 81
Categories of Legal Issues in Psychiatry 81
Civil Issues: Patient’s Rights 82
Civil Issues: Doctor–Patient Relationship 84
Criminal Issues: Competency and Insanity 88
Other Criminal Issues: Diminished Capacity and Mitigating Factors 91
Conclusion 92
Section II A Developmental Perspective on Normal Domains of Mental and Behavioral Functions 95
Section Editor: David A. Mrazek
Chapter 7 A Psychiatric Perspective on Human Development 97
David A. Mrazek
Biological Development Genetic Considerations 98
Neurological Considerations 98
Endocrinological Considerations 99
Cognitive Development 100
Emotional Development 101
Social Development 102
Moral Development 102
Developmental Psychopathology Risk and Protective Factors 104
High-Risk Periods for Psychopathology 106
Interlineal Decalage 106
The Psychiatrist as a Developmentalist 107
Chapter 8 Infant Development: The First 3 Years of Life 109
Charles H. Zeanah, Brian Stafford, Neil W. Boris, Michael Scheeringa
Theories and Models of Development and the First 3 Years of Life 109
Lines of Development and Their Discontinuities 113
Risk and Protective Factors 127
Illustrative Risk Conditions 128
Conclusion 131
Chapter 9 Preschool Development 135
Robert B. Clyman
Historic Considerations 135
Conceptual Framework 136
Lines of Development 136
Risk and Protective Factors 146
Developmental Psychopathology 147
Chapter 10 School-Age Development 150
Theodore Shapiro, Dima Amso
Conceptual Framework 151
Biological Development 151
Cognitive Development 152
Emotional Development 153
Sociocultural Development 154
Moral Development 155
Risk and Protective Factors 157
Developmental Psychopathology 157
Chapter 11 Adolescent Development 161
Kenneth E. Towbin, John E. Showalter
Historical Perspectives 162
Conceptual Framework 163
Biological Development 163
Brain Development 168
Cognitive Development 168
Emotional Development 172
Social Development 172
Risk Factors, Protective Factors, and Gene–Environment Interactions 175
Conclusion 178
Chapter 12 Adult Development 181
William R. Beardslee, George Vaillant
Towards a Conceptual Framework 181
Developmental and Cohort Effects 184
Risk Factors, Protective Factors, and Resilience 185
Young Adulthood as a Distinct Developmental Stage 186
An Integrated Model for Adult Development 187
Chapter 17  
Modeling Psychiatric Disorders in Experimental Animals  275  
Trevor W. Robbins, Holly M. Moore

Introduction  275  
Defining Phenotypes and Establishing Validity in Animal Models  277  
Dissecting Cognitive and Behavioral Endophenotypes from Complex Mental Disorders  278  
Using Neuropathological or Pharmacological Phenotypes to Test Etiologic and Pathogenic Hypotheses of Psychopathology  281  
“A Priori” Modeling Genetic, Environmental and Experiential Etiologies in Psychiatric Disorders  284  
Conclusions  286  

Chapter 18  
The Scientific Basis of Psychotherapy  289  
Steven Roose, Arnold M. Cooper, Peter Fonagy

The Scientific Basis of Psychotherapy  289  
Principles of Psychoanalysis: The Contribution of Freud  289  
Psychoanalysis after Freud  290  
Studies on the Effectiveness of Psychotherapies: Overall Efficacy of Treatment  292  
Biological and Neuroimaging Studies of Psychotherapy  295  
Conclusion  297  

Chapter 19  
The Neurobiology of Schizophrenia  301  
William V. Bobo, Judith L. Rapoport, Anissa Abi-Dargham, Hossein Fatemi, Herbert Y. Meltzer

Introduction  301  
Neurodevelopmental Concept  302  
Electrophysiological Abnormalities  311  
Conclusion  312  

Chapter 20  
Neurobiology of Anxiety Disorders  317  
Michael J. Meaney, Joseph E. LeDoux, Michael L. Liebowitz

Overview  317  
History and Clinical Picture of Anxiety Disorders  318  
Genetic Contributions to Anxiety Disorders  320  
Animal Models of Anxiety Disorders  320  
Pathophysiology of Anxiety Disorders  326  
Emotional Regulation: Role for the mPFC  326  
Therapeutic Targets: The Neurobiology of Coping  327  
Vulnerability for Anxiety Disorders  328  
Developmental Origins of Vulnerability for Anxiety Disorders  328  
Familial Transmission of Risk: Effects of Genes, Environment, and Their Interaction  329  
Conclusions  332  

Chapter 21  
Neurobiologic Foundations of Mood Disorders  339  
Ronald Duman, H. Jonathan Polan, Alan Schatzberg

Nomenclature  339  
Genetics  340  
Pathogenic Mechanisms  343  
Intracellular Signal Transduction Pathways and Growth Factors  346  
Conclusion  350  

Chapter 22  
Pathophysiology of Addiction  354  
George F. Koob, Denise Kandel, Nora D. Volkow

Clinical Picture  354  
Patterns of Substance Use and Substance Use Disorders  358  
Impact of Substance Use Disorders  360  
Vulnerability  363  
Neuropharmacology of Drug Intoxication and Reward  364  
Substance Dependence (Addiction)  367  

Chapter 23  
Neuroscience of Autism  379  
David G. Amaral, John L. R. Rubenstein, Sally J. Rogers

Introduction  379  
Diagnosis and Behavioral Features  380  
Medical and Other Comorbid Features  381  
Developmental and Genetic Mechanisms Implicated in the Etiology of Autism  382  
Neuropathology  385

Chapter 38  Behavior and Adaptive Functioning 633  
Susan C. Vaughan, John M. Oldham

Personality Style 633  
Domains of Functioning 639  
Assessing Behavior and Adaptive Functioning in the Clinical Interview 641  
Problematic Patterns of Behavior 642  
Conclusion 646

Chapter 39  Culture and Psychiatric Diagnosis 648  
Juan E. Mezzich, Roberto Lewis-Fernández, Maria Angeles Ruiperez

Introduction 648  
Specific Cultural Considerations 649  
The Case of Culture-Bound Syndromes and Idioms of Distress 654  
Conclusion 656

Section VI  Disorders 659  
Section Editor: Michael B. First

Chapter 40  Psychiatric Classification 661  
Michael B. First

Introduction 661  
Goals of a Classification System 661  
Approaches to Classification 661  
History of the DSM Classification System 663  
DSM-IV Overview 666  
DSM-IV Multiaxial System 666  
DSM-IV Classification and Diagnostic Codes 667  
Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence 673  
Delirium, Dementia, Amnestic Disorder, and Other Cognitive Disorders 674  
Mental Disorders due to a General Medical Condition Not Elsewhere Classified 674  
Substance-Related Disorders 674  
Schizophrenia and Other Psychotic Disorders 674  
Mood Disorders 675  
Anxiety Disorders 675  
Somatoform Disorders 675  
Factitious Disorders 675  
Dissociative Disorders 675  
Sexual and Gender Identity Disorders 675  
Eating Disorders 675  
Sleep Disorders 676  
Impulse-Control Disorders Not Elsewhere Classified 676  
Adjustment Disorders 676  
Personality Disorders 676  
Other Conditions That May Be a Focus of Clinical Attention 676  
Appendix Categories 677

Chapter 41  Diagnostic Classification in Infancy and Early Childhood 679  
Stanley I. Greenspan, Serena Wieder

An Interdisciplinary Approach to Classification 680  
The Need for a Comprehensive Multidimensional Developmental Approach 680  
Multidimensional Classification Based on the DIR Model 681  
Unique Features of the ICDL-DMIC Multiaxial System 681  
Selecting a Primary Diagnosis 682  
Clinical Thresholds for Diagnosis 682  
Axis I: Primary Diagnosis 683  
Conclusion 688

Chapter 42  Childhood Disorders: Intellectual Disability 689  
Kerim M. Munir, Sandra L. Friedman, Maija L. Wil ska, Ludwik S. Szymanski

Introduction 689  
Intellectual Disability 689  
Concept of Intellectual Disability 689  
Definitions of Intellectual Disability and Its Scientific Evolution 690  
Patterns of Comorbidity 692  
Etiology and Pathophysiology of Intellectual Disability 694  
Course and Natural History of Intellectual Disability 708  
Habilitation and Treatment Approaches to Intellectual Disability 709  
Prevention of Intellectual Disability 713  
Mental Disorders in Persons with Intellectual Disability 714
## Contents

- Prevalence of Psychopathology in Persons with Intellectual Disability 714
- Intellectual Disability and Behavioral Patterns 715
- Diagnosis of Mental Disorders in Persons with Intellectual Disability 717
- Diagnosis of Specific Mental Disorders 723

**Childhood Disorders: Learning and Motor Skills Disorders** 747

*Larry B. Silver*

- Definitions 747
- Diagnosis 748
- The Educational Curriculum and Diagnosis 751
- Differential Diagnosis 752
- The Cortical Disorders 756
- Social Problems 756
- Differences in Developmental, Gender, and Cultural Presentations 757
- Etiology 757
- Treatment 758
- Summary 761
- Special Considerations in the Doctor–Patient Relationship 762
- Comparison of DSM IV/ICD-10 Diagnostic Criteria 762

### Chapter 44

**Childhood Disorders: Communication Disorders** 765

*William M. Kykylo*

- Introduction 765
- Expressive and Mixed Expressive-Receptive Language Disorders 765
- Demographic and Cultural Issues in Treatment 773
- Phonological Disorder 773
- Stuttering 774
- Communication Disorder Not Otherwise Specified 776

### Chapter 45

**Childhood Disorders: The Pervasive Developmental Disorders** 779

*James McPartland, Ami Klin, Alexander Westphal, Fred R. Volkmar*

- Introduction 779
- Autistic Disorder 779
- Asperger’s Disorder 791
- Childhood Disintegrative Disorder 795
- Rett’s Disorder 796
- Pervasive Developmental Disorder—Not Otherwise Specified 799
- Summary 800

### Chapter 46

**Childhood Disorders: Attention-Deficit and Disruptive Behavior Disorders** 804

*Jeffrey H. Newcorn, Iliyan Ivanov, Vanshdeep Sharma, Kurt Schulz, Jeffrey M. Halperin*

- Introduction 804
- Diagnosis 804
- Attention-Deficit/Hyperactivity Disorder 805
- Etiology and Pathophysiology 813
- Treatment 817
- Conclusions 826

### Chapter 47

**Childhood Disorders: Feeding and Related Disorders of Infancy or Early Childhood** 830

*Rachel J. Bryant-Waugh, Emma H. C. Piepenstock*

- Introduction 830
- Feeding Disorder of Infancy or Early Childhood 831
- Diagnosis 831
- Assessment 833
- Epidemiology 834
- Comorbidity 834
- Course 835
- Differential Diagnosis 835
- Etiology and Pathophysiology 835
- Treatment 836
- Rumination Disorder 839
- Diagnosis 839
- Assessment 840
- Epidemiology 840
- Course 840
- Differential Diagnosis 840
- Etiology and Pathophysiology 841
- Treatment 841
### Chapter 48: Childhood Disorders: Tic Disorders

Matt W. Specht, Courtney Pierce Keeton, John T. Walkup

- Diagnosis 847
- Epidemiology 850
- Etiology and Pathophysiology 852
- Treatment 856
- Treatment of Co-occurring Psychiatric Disorders in TD 861
- Treatment-Refractory Cases 862
- Conclusion 864

### Chapter 49: Childhood Disorders: Elimination Disorders and Childhood Anxiety Disorders

Christopher P. Lucas, David Shaffer

- Enuresis 868
- Encopresis 875
- Other Disorders Specific to Children and Adolescents 879
- SAD 879
- Selective Mutism 883
- Comparison of DSM-IV/ICD-10 Diagnostic Criteria 885

### Chapter 50: Stereotyped Movement and Reactive Attachment Disorder

Morgan Feilbelman, Charles H. Zeanah

- Stereotyped Movement Disorder 889
- Diagnosis 889
- Assessment 889
- Epidemiology 890
- Comorbidity 890
- Etiology and Pathophysiology 890
- Treatment 891
- Reactive Attachment Disorder 892
- Diagnosis 892
- Assessment 893
- Epidemiology 893
- Comorbidity 893
- Course 893
- Differential Diagnosis 894
- Etiology 894
- Treatment 895

### Chapter 51: Dementia, Delirium, and Other Cognitive Disorders

Robert L. Frierson

- Dementia 898
- Degenerative Causes of Dementia 902
- Infectious Causes of Dementia 911
- Dementia due to Head Trauma 914
- Substance-Induced Persisting Dementia 915
- Dementia due to Other General Medical Conditions 916
- Delirium 917
- Amnestic Disorders 924

### Chapter 52: Mental Disorders Due to a General Medical Condition

David P. Moore

- Introduction 931
- Psychotic Disorder Due to a General Medical Condition 932
- Mood Disorder Due to a General Medical Condition 935
- Anxiety Disorder Due to a General Medical Condition with Panic Attacks or with Generalized Anxiety 940
- Mental Conditions Due to a General Medical Disorder Not Elsewhere Classified 942
- Personality Change Due to a General Medical Condition 944
- Mental Disorder Not Otherwise Specified Due to a General Medical Condition 947

### Chapter 53: General Approaches to Substance and Polydrug Use Disorders

Thomas R. Kosten

- Definition 957
- Diagnosis and Assessment 959
- Epidemiology 963
- Course and Natural History 964
- Etiology and Pathophysiology 964
- Standard Treatments 967
- Special Treatment Features 968
Chapter 54  Substance Abuse: Alcohol Use Disorders  971

Thomas F. Babor, Carlos A. Hernandez-Avila, Jane A. Ungemack

Definition  971
Etiology and Pathophysiology  971
Assessment and Differential Diagnosis  974
Epidemiology and Comorbidity  983
Course and Natural History  988
Treatment  988
Conclusion  999

Chapter 55  Substance Abuse: Amphetamine Use Disorders  1005

Kevin A. Sevarino

Diagnosis  1006
Epidemiology  1008
Etiology  1011
Treatment  1012
Comparison of DSM-IV-TR/ICD-10 Diagnostic Criteria  1014

Chapter 56  Substance Abuse: Caffeine Use Disorders  1019

Roland R. Griffiths, Chad J. Reissig

Introduction  1019
Caffeine Intoxication  1019
Caffeine Withdrawal  1024
Caffeine Dependence  1029
Caffeine-Induced Anxiety Disorder  1033
Caffeine-Induced Sleep Disorder  1035
Conclusion  1037

Chapter 57  Substance Abuse: Cannabis-Related Disorders  1041

Benjamin R. Nordstrom, Frances R. Levin

Introduction  1041
Epidemiology of Cannabis Abuse and Dependence  1041
Endocannabinoid System  1043
Treatment of Cannabis Related Disorders  1047
Pharmacotherapy in Cannabis Self Administration or Intoxication  1053
Conclusion  1055

Chapter 58  Substance Abuse: Cocaine Use Disorders  1058

Jennifer R. Baker, Charles Y. Jin, Elinore F. McCance-Katz

Introduction  1058
Epidemiology  1058
Course and Natural History  1060
Etiology and Pathophysiology  1061
Diagnosis of Cocaine Use Disorders  1062
Treatment of Cocaine Use Disorders  1066
Assessment and Treatment Overview  1067
Cocaine Use Disorders: Clinical Course  1067
Overview of Treatment for Cocaine Use Disorders  1068
Pharmacotherapies for Cocaine Use Disorders  1072
Common Problems in Management  1077
Psychiatric Comorbidity  1079
Comorbid Mood Disorders or Attention Deficit Hyperactivity Disorder  1079
Antisocial Personality Disorder  1080
Comparison of DSM-IV/ICD-10 Diagnostic Criteria  1081

Chapter 59  Substance Abuse: Phencyclidine Use Disorders  1090

Daniel C. Javitt

Epidemiology  1090
Etiology and Pathophysiology  1092
Diagnosis and Differential Diagnosis  1093
Assessment  1095
Standard Approach to Treatment  1096
Special Features Influencing Treatment  1097

Chapter 60  Substance Abuse: Hallucinogen- and MDMA-Related Disorders  1100

Rif S. El-Mallakh, John H. Halpern, Henry D. Abraham

Introduction  1100
Ethnobotanical Hallucinogens  1100
Synthetic Hallucinogens  1102
Human Experimentation with Hallucinogens  1102
MDMA (Ecstasy)  1102
Hallucinogen Intoxication  1103
Hallucinogen Abuse  1107
LSD-Related Psychotic Disorders  1108
Hallucinogen Persisting Perception Disorder (HPPD) 1110

Chapter 61 Substance Abuse: Inhalant-Related Disorders 1127
Charles W. Sharp, Neil Rosenberg, Fred Beauvais

Introduction 1127
Substances Inhaled 1127
Inhalant Use Disorders 1130
Inhalant-Induced Disorders 1131
Psychiatric Disturbances Associated with Organic Solvent Abuse 1132
Etiology and Pathophysiology 1132
Clinical Manifestations After Chronic Inhalant Abuse 1133
Treatment 1140
Comparison of DSM-IV-TR/ICD-10 Diagnostic Criteria 1142
A Tribute to Dr. Neil Rosenberg 1142

Chapter 62 Substance Abuse: Nicotine Dependence 1149
Douglas Ziedonis, Marc L. Steinberg, Susan J. Fiester, Cezar Cimpeanu

Diagnosis 1149
Definition and Diagnostic Features 1149
Assessment 1150
Epidemiology 1151
Comorbidity Patterns 1152
Course 1153
Differential Diagnosis 1153
Differences in Developmental, Gender, and Cultural Presentation 1153
Etiology and Pathophysiology 1153
Treatment 1155
Treatment Benefits 1157
Somatic Treatments 1157
Psychosocial Treatments 1160
Brief or Minimal Medical Professional-Delivered Interventions/Advice 1160
Combined Psychosocial and Psychopharmacological Therapies 1162
Problems in Management 1162
Special Considerations in Treatment 1163

Chapter 63 Substance Abuse: Opioid Use Disorders 1169
George E. Woody, Paul J. Fudala

Introduction 1169

Chapter 64 Substance Abuse: Sedative, Hypnotic, or Anxiolytic Use Disorders 1186
Donald R. Wesson, David E. Smith, Walter Ling, Sanjay Sabnani

Introduction 1186
Sedative–Hypnotic Related Disorders 1186
Sedative–Hypnotics and GABA Receptors 1187
Abuse and Abuse Potential 1188
Withdrawal Syndrome 1192
Evaluation and Diagnosis 1194
Treatment 1195
Comparison of DSM-IV-TR/ICD-10 Diagnostic Criteria 1198

Chapter 65 Schizophrenia and Other Psychoses 1201
Jayendra K. Patel, Debra A. Pinals, Alan Breier

Historical Overview 1201
Diagnosis 1203
Epidemiology 1207
Etiology 1211
Clinical Manifestations and Phenomenology 1230
Differential Diagnosis 1233
Course of Illness 1239
Other Psychotic Disorders 1265
Schizoaffective Disorder 1265
Brief Psychotic Disorder 1268
Schizophréniform Disorder 1270
Shared Psychotic Disorder 1276
Comparison of DSM-IV/ICD-10 Diagnostic Criteria 1278

Chapter 66 Mood Disorders: Depression 1283
Heinz Grunze, Cornelius Schüle, David Casey, Thomas C. Baghai

Diagnosis 1283

Chapter 73  Anxiety Disorders: Generalized Anxiety Disorder 1494
Amy E. Lawrence, Timothy A. Brown

Introduction 1494
Diagnosis 1494
Assessment 1495
Epidemiology 1497
Etiology and Pathophysiology 1500
Treatment 1502
Summary 1506

Chapter 74  Somatoform Disorders 1510
Sean H. Yutzy, Brooke S. Parish

Introduction 1510
Differential Diagnosis 1511
Differentiation Among the Various Somatoform Disorders 1513
Epidemiology 1513
Treatment 1513
Somatization Disorder 1513
Definition and Diagnostic Features 1513
Epidemiology 1518
Course 1518
Differential Diagnosis 1518
Etiology and Pathophysiology 1521
Treatment 1521
Undifferentiated Somatoform Disorder 1523

Chapter 75  Factitious Disorders 1548
Anne M. Fleming, Stuart J. Eisendrath

Introduction 1548
Factitious Disorder 1549
Diagnosis 1549
Assessment 1551
Epidemiology 1551
Comorbidity Patterns 1551
Course 1552
Differential Diagnosis 1552
Etiology and Pathophysiology 1552
Treatment 1553
Factitious Disorder by Proxy 1554
Diagnosis 1554
Assessment 1555
Epidemiology 1555
Comorbidity Patterns 1555
Course 1555
Differential Diagnosis 1555
Etiology and Pathophysiology 1555
Treatment 1555
Summary 1556

Chapter 76  Dissociative Disorders 1558
José R. Maldonado, David Spiegel

Development of the Concept 1558
Epidemiology 1559
Diagnostic Criteria and Treatment 1560
Treatment 1567
Theoretical and Research Issues: Models and Mechanisms of Dissociation 1573
Comparison of DSM-IV-TR/ICD-10 Diagnostic Criteria 1574
Conclusion 1574

Chapter 77  Sexual Disorders 1578
Stephen B. Levine

Preface 1578
The Components of Sexuality 1579
Sexual Development Through the Life Cycle 1580
The Sexual Dysfunctions 1580
Significance of Sexual Dysfunction 1580
DSM-IV-TR Diagnoses 1580
Epidemiology 1580
Sexual Equilibrium 1581
The Nature of Sexual Desire 1581
The Problems of Sexual Arousal 1586
Problems with Orgasm 1589
Sexual Pain Disorders 1592
Sexual Dysfunction Not Otherwise Specified 1594
Gender Identity Disorders 1594
Extremely Feminine Young Boys 1594
Masculine Girls: Tomboys 1595
The Subjectivity of a Well-Developed Gender Disorder 1595
Diagnostic Criteria of Gender Identity Disorder 1596
Diagnostic Criteria of GIDNOS 1597
The Relationship of GIDs to Orientation 1598
Treatment Options for the GIDs 1598
The Paraphilias 1600
Three General Characteristics of the Paraphilias 1600
Speculations About the Underlying Problem 1601
The Specific Paraphilias 1602
Treatment 1604
Sexual Disorder Not Otherwise Specified 1606
The Doctor–Patient Relationship and Sexual Disorders 1606
Final Thoughts 1606
Comparison of DSM-IV/ICD-10 Diagnostic Criteria 1606

Chapter 78  Eating Disorders 1609
B. Timothy Walsh

Introduction 1609
Anorexia Nervosa 1609
Diagnosis 1609
Etiology and Pathophysiology 1615
Treatment 1616
Bulimia Nervosa 1618
Definition and Diagnostic Features 1618
Etiology and Pathophysiology 1620
Treatment 1621
Binge-Eating Disorder 1623
Diagnosis 1623
Etiology and Pathophysiology 1624
Treatment 1624

Chapter 79  Sleep and Sleep–Wake Disorders 1626
Milton Erman, Sonia Ancoli-Israel

Phenomenology and Organization of Sleep 1626
Physiological Regulation of Sleep and Wakefulness 1626
Normal Age-Related Changes in Sleep and Wakefulness 1628
Neurophysiology and Neurochemistry of Sleep 1629
Contents

Sleep Disorders 1629
General Approach to the Patient with a Sleep Disorder 1630
Role of the Sleep Laboratory in Clinical Sleep Disorders 1631
Chronic Insomnia 1632
General Approaches to the Clinical Management of Sleep Disorders in Psychiatric Patients 1637
Hypersomnia 1638
Breathing Related Sleep Disturbances (BRSD) 1641
Circadian Rhythm Sleep Disorder (Sleep–Wake Schedule Disorders) 1643
Shift Work Sleep Disorder 1645
Jet Lag 1645
PLMS and Restless Legs Syndrome (RLS) 1646
Parasomnias 1647
Sleep Disorders Due To a General Medical Condition 1650
Substance-Induced Sleep Disorder 1651
Comparision of DSM-IV-TR /ICD-10 Diagnostic Criteria 1656

Chapter 80 Impulse-Control Disorders 1658
Daphne Simeon, Heather Berlin
Introduction 1658
Intermittent Explosive Disorder 1661
Kleptomania 1668
Pyromania and Fire Setting Behavior 1674
Pathological Gambling 1678
Trichotillomania 1687
Comparision of DSM-IV/ICD-10 Diagnostic Criteria 1695

Chapter 81 Adjustment Disorders 1702
James J. Strain, Kim Kipstein, Jeffrey H. Newcorn
Definition 1702
Epidemiology 1705
Etiology 1706
Diagnosis and Differential Diagnosis 1707
Course and Natural History 1709
Treatment 1710
Refractory Patients and Nonresponse to Initial Treatment 1713
Conclusion 1713
Comparision of DSM-IV/ICD-10 Diagnostic Criteria 1714

Chapter 82 Personality Disorders 1718
Thomas A. Widiger, Stephanie N. Mullins-Sweatt
Personality Disorder 1718
Paranoid Personality Disorder 1724
Schizoid Personality Disorder 1726
Schizotypal Personality Disorder 1728
Antisocial Personality Disorder 1730
Borderline Personality Disorder 1733
Histrionic Personality Disorder 1735
Narcissistic Personality Disorder 1737
Avoidant Personality Disorder 1740
Dependent Personality Disorder 1742
Obsessive-Compulsive Personality Disorder 1744
Personality Disorder, Not Otherwise Specified 1746

Chapter 83 Psychological Factors Affecting Medical Condition 1754
James L. Levenson
Definition 1754
Assessment and Diagnosis 1755
Differential Diagnosis 1757
Epidemiology and Comorbidity 1757
Course 1758
Etiology and Pathophysiology 1758
Treatment 1758

Chapter 84 Medication-Induced Movement Disorders 1773
Thomas W. Meeks, Dilip V. Jeste
Introduction 1773
Historical Background 1773
Classification 1773
Informed Consent/Medicolegal Issues 1774
Acute Neuroleptic-Induced Movement Disorders 1774
Neuroleptic-Induced Acute Dystonia 1774
Neuroleptic-Induced Parkinsonism 1776
Neuroleptic-Induced Acute Akathisia 1779
Prophylactic Anticholinergic Medication: Pros and Cons 1780
Neuroleptic-Induced Tardive Movement Disorders 1781
Neuroleptic-Induced Tardive Dyskinesia 1781
Other Tardive Movement Disorders 1785
Chapter 96

Psychosocial Rehabilitation 2047

Alan S. Bellack

Psychosocial Rehabilitation 2047
Issues in the Design of Psychosocial Interventions 2048
Timing and Duration of Treatment 2048
Individual Differences in Treatment Needs 2048
The Role of the Person 2049
Impairments in Information Processing 2050
Adoption of a Compensatory Model 2051
Rehabilitation Strategies 2051
Social Skills Training 2051
Cognitive Rehabilitation 2053
Vocational Rehabilitation 2054
Summary and Conclusions 2055

Chapter 97

Psychiatric Rehabilitation for Achieving Successful Community Living for Adults with Psychiatric Disabilities 2059

Phyllis Solomon, Sara W. Cullen

Defining Adults with Psychiatric Disabilities 2059
Prevalence Estimates Of Psychiatric Disability 2060
Defining Psychiatric Rehabilitation 2061
Development of Psychiatric Rehabilitation 2061
Principles and Service Elements of Psychiatric Rehabilitation 2062
Examples of Psychiatric Rehabilitation Practices 2062
Recovery and Rehabilitation 2065
Psychotherapeutic Evidence-Based Practices 2067
Conclusion 2080

Chapter 98

Advocacy, Self-Help, and Consumer-Operated Services 2083

Harriet P. Leffey

Introduction 2083
Conceptual Distinctions 2083
Citizen and Family Advocacy Movements 2085
Citizen Advocacy Organizations 2086
Stakeholder (Family and Consumer) Organizations 2086
Consumer Self-Help and Advocacy Organizations 2088

Chapter 99

General Principles of Pharmacologic Therapy 2099

Zahinoor Ismail, Bruce G. Pollock

Introduction 2099
Pharmacokinetics 2099
Pharmacodynamics 2105
Safety and Efficacy 2107
Summary 2109

Chapter 100

Psychopharmacology: Ethnic and Cultural Perspectives 2112

Keh-Ming Lin, Chia-Hui Chen, Shu-Han Yu, Margaret T. Lin, Michael W. Smith

Dispelling the “Color-Blind” Approach 2112
The Cultural Context of Psychopharmacotherapy 2113
Clinicians’ Attitudes 2113
Adherence 2113
Expectation (“Placebo”) Effects 2114
The Concomitant Use of Alternative/Indigenous Treatment and Healing Methods 2115
Biological Diversity and Its Consequence in Psychotropic Responses 2115
Genetic Polymorphism of Genes Encoding “Drug-Metabolizing Enzymes” 2116
Factors Affecting the Expression of Drug-Metabolizing Enzymes 2117
Genetic Polymorphism of Genes Encoding Receptors, Transporters, or Other Therapeutic Targets 2119
Genetic Polymorphism of Other Genes Affecting Pharmacological Responses 2119
Summary and Future Research Directions 2120
# Chapter 101 Antidepressants 2123

*Robert J. Boland, Martin B. Keller*

Theoretical Basis for Treatment 2123
The Basis for Determining Efficacy 2128
The Formulation of Treatment 2131
Initiation of Treatment 2143
Phases of Treatment 2147
Conclusions 2151

# Chapter 102 Antipsychotic Drugs 2161

*Seiya Miyamoto, David B. Merrill, Jeffrey A. Lieberman, W. Wolfgang Fleischacker, Stephen R. Marder*

Introduction 2161
History of Antipsychotic Drug Development 2161
Mechanism of Action of Antipsychotic Agents 2162
Pharmacology of Antipsychotic Agents 2166
Conditions Treated with Antipsychotic Medications 2170
Effects of Antipsychotic Agents on Symptoms of Schizophrenia 2174
Treatment of Different Phases of Schizophrenia 2177
Use of Plasma Levels of Antipsychotic Drugs 2183
Drug Interactions and Antipsychotic Agents 2183
Antipsychotic Medications and Pregnancy 2183
Adverse Effects 2184
Future Directions in Antipsychotic Drug Research and Treatment 2192
Conclusions 2193

# Chapter 103 Mood Stabilizers 2202

*David J. Muzina, David E. Kemp, Joseph R. Calabrese*

Introduction 2202
Defining Mood Stabilizers 2202
Mood Stabilizers for Acute Mania 2203
Mood Stabilizers for Acute Bipolar Depression 2210
Mood Stabilizers for Maintenance Treatment of Bipolar Disorder 2214
Mood Stabilizers for Rapid Cycling Bipolar Disorder (RCBD) 2218
Redefining Mood Stabilizers 2219
Conclusion 2219

# Chapter 104 Anxiolytic Drugs 2223

*Deidre M. Edwards, Kathryn L. Hale, Rachel E. Maddux, Mark Hyman Rapaport*

Introduction 2223
A General Approach to Using Medication with Anxious Patients 2223
Antidepressant Medication 2224
Benzodiazepine Medication 2225
Buspirone 2225
Beta-Blocker Medication 2226
Anticonvulsant Medication 2226
Antipsychotic Medication 2226
Generalized Anxiety Disorder 2228
Social Anxiety Disorder 2233
Panic Disorder 2236
Posttraumatic Stress Disorder 2240
Obsessive–Compulsive Disorder 2244
Future Directions 2248
Conclusion 2248

# Chapter 105 Pharmacologic Treatment of Insomnia 2254

*David N. Neubauer*

Introduction 2254
Sleep–Wake Cycle Regulation 2254
Historical Overview 2255
FDA-Approved Insomnia Treatment Medications 2255
Prescription Medication Off-Label Use 2258
OTC Medications 2260
Complementary and Alternative Substances 2261
Insomnia in Psychiatric Patients 2261
Summary or Conclusions 2262

# Chapter 106 Stimulants 2264

*Natalya Paykina, Laurence L. Greenhill, Kelly N. Fahl, J. Craig Nelson*

Treatment of Children with Disruptive Behavior Disorders 2264
Natalya Paykina, Laurence L. Greenhill, Kelly N. Fahl

Medications 2264
Pharmacology 2266
Indications and a Review of Efficacy Data in Children 2269
Side Effects 2276
Clinical Use 2279
Treatment of Adult Depression 2284
J. Craig Nelson

Chapter 107 Cognitive Enhancers and Treatments for Alzheimer’s Disease 2294
Roy Yaari, Pierre N. Tariot, Lon S. Schneider

Chapter 108 Complementary and Alternative Treatments in Psychiatry 2318
Richard P. Brown, Patricia L. Gerbarg, Philip R. Muskin

Chapter 109 Brain Stimulation in Psychiatry 2354
Stefan Rowny, Sarah H. Lisanby

Brain Stimulation Tools in Psychiatry 2358
Conclusions and Future Directions 2368

Chapter 110 Pharmacologic Management of Treatment-Resistant Unipolar Depression 2372
Patrick J. McGrath, Jeffrey M. Miller

Chapter 111 Pharmacological Treatment of Substance Abuse Disorders 2390
Wilfrid Noel Raby, Frances R. Levin, Edward V. Nunes

Chapter 112 Pharmacologic Issues During Pregnancy 2417
Kimberly A. Yonkers, Margaret Spinelli

Introduction 2417
Stress, Mood, and Adverse Birth Outcomes 2417
In Utero Exposure to Antidepressants and Birth Outcomes 2418
Psychotherapy 2421
Pharmacotherapy During Lactation 2423
Management Recommendations 2425
Summary 2426
Chapter 113  Combined Treatment with Medications and Psychotherapy  2430  
Bret R. Rutherford, Deborah L. Cabaniss, Steven P. Roose  
- History of Combined Treatments  2430  
- Evidence for Combined Treatments  2431  
- Technical Considerations in Doing Combined Treatment  2439  
- Conclusions  2444  

Chapter 114  Patient Compliance  2447  
Stephanie A. Riolo, Christina G. Weston  
- Introduction  2447  
- Definition: “Compliance” versus “Adherence”  2447  
- Treatment Refusal  2448  
- Overview of Theoretical Models  2448  
- Prevalence of Medication Noncompliance  2449  
- Patterns of Medication Noncompliance  2449  
- Measurement of Medication Compliance  2450  
- Risk Factors for Noncompliance  2451  
- Specific Patient Populations  2455  
- Intervention Strategies  2457  
- Conclusions  2459  

Section IX  Special Populations and Settings  2463  
Section Editor: Michelle B. Riba  

Chapter 115  Managing Psychological Consequences in Disaster Populations  2465  
Derrick A. Hamaoka, David M. Benedek, Robert J. Ursano  
- Disaster Psychiatry  2465  
- Conclusion  2474  

Chapter 116  Management of the Suicidal Patient  2478  
Glenn A. Melvin, Kelly Posner, Barbara H. Stanley, Maria A. Oquendo  
- Introduction  2478  
- What is Suicidal Ideation and Behavior?  2478  
- Scope of The Problem of Suicidal Behavior: Mortality and Morbidity  2478  
- Risk and Protective Factors  2479  
- Demographic Risk and Protective Factors  2479  

Chapter 117  Restraints and Seclusion  2491  
Wanda K. Mohr, Kevin Ann Huckshorn, Kim J. Masters  
- Controversies Regarding Restraint and Seclusion  2491  
- State of Research  2491  
- The Legal Rights of Psychiatric Patients  2493  
- The State of Education  2493  
- Conclusion  2494  

Chapter 118  Psychosomatic Medicine  2496  
James L. Levenson  
- Introduction  2496  
- History  2496  
- International Developments in Psychosomatic Medicine  2497  
- Psychosomatic Medicine as a Scholarly Discipline  2497  
- The Clinical Practice of Psychosomatic Medicine  2498  
- Psychiatric Diagnosis in the Medically Ill  2498  
- Psychosomatic Aspects of Cardiovascular Disease  2499  
- Psychosomatic Aspects of Cancer  2501  
- Psychosomatic Aspects of Endocrine Disorders  2503  
- Conclusion  2505  

Chapter 119  Psychiatric Conditions in Women during Reproductive Transitions  2507  
Helen G. Kim, Nancy Raymond, Susan G. Kornstein  
- Pregnancy  2507  
- Postpartum Psychiatric Illness  2509  
- Menopause  2511  
- Conclusion  2513  

Chapter 120  Death and Bereavement  2516  
M. Katherine Shear  
- Introduction  2516
## Contents

- Death and Dying 2516
  - Bereavement and Grief 2519

### Chapter 121
- Serving People Who Have Mental Illness and Homelessness 2526
  - Hunter L. McQuistion, Alan D. Felix, Judith Samuels
  - Background: The Evolution of Services 2526
  - The Stages of Care 2530
  - Administration, Academics, and Advocacy 2534

### Chapter 122
- Gender Identity and Sexual Orientation 2538
  - Robert P. Cabaj
  - Definitions and Concepts 2538
  - History of Homosexuality and Psychiatry 2539
  - Biology, Genetics, and Cultural Perspectives on Homosexuality and Bisexuality 2540
  - Developmental Issues Facing Most Gay, Lesbian, and Bisexual People 2541
  - Psychotherapy: Special Considerations 2542
  - Gender Identity and Transgender Issues 2546

### Chapter 123
- Management of the Patient in Geriatric Psychiatry 2549
  - David A. Casey
  - Introduction 2549
  - Approach to the Patient 2549
  - Management of Dementia 2551
  - Management of Behavioral Disturbance in Dementia 2554
  - Etiology of Behavioral Disturbance 2554
  - Management of Depression in the Elderly 2557
  - Conclusion 2560

### Chapter 124
- Management of Victims of Torture 2563
  - Marianne C. Kastrup, James M. Jaranson
  - Introduction 2563
  - Medical Aspects of Torture 2565
  - Identifying Consequences of Torture and Need for Treatment 2566
  - General Therapeutic Considerations 2568
  - Treatment Interventions 2570
  - Organization of Care 2572
  - Specific Populations and Issues 2572
  - Conclusions 2574

### Chapter 125
- Psychiatric Management of Victims of Physical and Sexual Abuse and Rape 2576
  - Donna E. Stewart, Simone N. Vigod
  - Introduction 2576
  - Epidemiology 2577
  - Management—Acute Presentations of Physical or Sexual Abuse and Rape 2578
  - Long-Term Mental Health Sequelae of Physical and Sexual Abuse and Rape 2584
  - Management Considerations for Long-Term Psychiatric Sequelae of Physical and Sexual Abuse and Rape 2586
  - Conclusions 2591

### Chapter 126
- Correctional Psychiatry 2593
  - Erik J. Roskes
  - Epidemiology of Mental Illness in Correctional Populations 2593
  - Criminal Justice/Mental Health Collaborative Interventions 2595
  - Legal Considerations 2596
  - Mental Health Care in the Correctional Setting 2596
  - Special Topics and Challenges in the Correctional Setting 2598
  - Conclusion 2600

### Chapter 127
- Treatment of Violent Behavior 2602
  - Fabian M. Saleh, John P. Fedoroff, Adekunle G. Ahmed, Debra A. Pinals
  - Introduction 2602
  - Assessment of Violence Risk in Clinical Settings 2602
  - Classification of Violence 2603
  - Link Between Anger and Aggression 2603
  - Clinical Factors Associated with Violence 2603
  - Violence, Physiology, and Biology 2605
  - Treatment of Aggression 2608
  - Conclusions 2612

Preface to this Edition

Time and science march on, and thus, a new edition of *Psychiatry* is now before you. The advances in our field continue at a rapid pace, with an ongoing transformation of our understanding of brain and mental functioning, and the development of ever more sophisticated treatments. We continue to feel tremendous gratitude to our colleagues, whose acceptance of *Psychiatry* has led to it becoming a leading reference text around the world.

This edition is marked not only by extensive revision of all chapters, and by the addition of many new chapters, but also by a major restructuring of the book. Where before there were seven major sections, there are now nine, reflecting both the expansion of our knowledge base, and what we believe will be a more useful organization of the material.

With all the revising and restructuring though, our philosophical preference continues to emphasize an integrative approach to both understanding psychopathology and providing treatment. And, as always, we hold to the view that the context of our understanding and intervention remains the therapeutic alliance we develop and maintain with our patients.

You will also see that we have expanded our panel of editors, reflecting both the breadth of the field, and the increasingly international scope of our work. Our two new editors are Michael First, MD and Mario Maj, MD. Professor Michael First in New York is an internationally known psychiatrist in the area of diagnostic classification, and one of the leaders in the development of the DSM-IV and DSM-IV-TR. Professor Mario Maj is chair of psychiatry at the University of Naples, Italy, an internationally known scholar in several areas, and incoming president of the World Psychiatric Association.

*Psychiatry*’s success and international acceptance reflects the outstanding contributions of several hundred of the most eminent and scholarly group of colleagues with whom one could ever hope to work. As always, their diligence and commitment to excellence made the work of the section editors and editors much easier than one might imagine. Great thanks go to all the authors and section editors, who deserve the highest accolades for the quality of this work.

Thanks also go to all those at Wiley-Blackwell involved in the publication of this work. Special thanks go to Joan Marsh, Andrew Spong, Layla Paggetti, Jill Hawthorne, and Kerry Powell for their commitment to the project. None of the editors could have accomplished their work without the devoted assistance of their home-based secretaries and assistants, all of whom have our thanks.

Most importantly, special thanks go to our families, who, once again, tolerated hours of our reviewing manuscripts and correcting proofs, hours which otherwise would have been spent with them.

ALLAN TASMAN, MD
JERALD KAY, MD

MICHAEL B. FIRST, MD
MARIO MAJ, MD
This is an exciting time in the field of psychiatry. Scientific progress has expanded the diagnostic and therapeutic capabilities of psychiatry at the same time that psychiatry has begun to play a larger role in the delivery of care to a wider population, both in mental health and in primary care settings. Psychiatry at the end of the 20th century plays an important role among the medical specialties.

The physician-patient relationship provides the framework for quality psychiatric practice. The skilled clinician must acquire a breadth and depth of knowledge and skills in the conduct of the clinical interaction with the patient. To succeed in this relationship, the psychiatrist must have an understanding of normal developmental processes across the life cycle (physiological, psychological, and social) and how these processes are manifested in behavior and mental functions. The psychiatrist must also be expert in the identification and evaluation of the signs and symptoms of abnormal behavior and mental processes and be able to classify them among the defined clinical syndromes that constitute the psychiatric nosology.

To arrive at a meaningful clinical assessment, one must understand the etiology and pathophysiology of the illness along with the contributions of the patient’s individual environmental and sociocultural experiences. Furthermore, the psychiatrist must have a command of the range of therapeutic options for any given condition, including comparative benefits and risks, and must weigh the special factors that can influence the course of treatment such as medical comorbidity and constitutional, sociocultural, and situational factors.

The view of psychiatric practice just described forms the framework for Psychiatry. Section I, Approaches to the Patient, describes the importance of therapeutic listening and the development of the skills and knowledge necessary to assess and manage the interpersonal context in which psychiatric treatment occurs. Section II, A Developmental Perspective on Normal Domains of Mental and Behavioral Function, provides a review of normal development from a variety of perspectives across the life cycle. Section III, Scientific Foundations of Psychiatry, follows with a review of the scientific knowledge on which our understanding of behavior and mental functions, as well as psychopathology, is based.

Because we believe that good clinical practice must be based on comprehensive and sophisticated clinical assessment, Section IV, Manifestations of Psychiatric Illness, provides a detailed review of clinical assessment. What logically follows in Section V, which constitutes the heart of Psychiatry, is the discussion of psychiatric disorders. This section, which follows the nosology of the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, differs from that found in other textbooks by the depth of the discussion of the clinical management of patients with each of these disorders. Unlike other texts, we have included substantial information on practical management; descriptions of common problems in management, including the treatment of refractory conditions; and discussions of typical issues that arise in the physician-patient relationship as treatment progresses.

The chapters in Section VI, Therapeutics, reflect our view that psychiatrists must be knowledgeable about a wide range of treatment options that include both somatic and psychotherapeutic interventions. The final section of the book, Section VII, Special Clinical Settings and Problems, reflects our belief that the sociocultural context within which the patient lives is a central aspect of the treatment process. Thus, we have included discussions of legal issues, reimbursement systems, ethical standards, the role of peer support and consumer advocacy, and the development of innovative non-hospital-based treatment programs.

Because no one should practice psychiatry without an appreciation of how the current knowledge base and treatment modalities have evolved historically, Appendix I, A Brief History of Psychiatry, provides a highly readable and scholarly review of the history of modern psychiatry. Because lifelong learning and the acquisition of new knowledge and skills are essential to optimal clinical practice, Appendix II, Research Methodology and Statistics, and Appendix III, Continued Professional Development, provide valuable information needed to assess the scientific worth of newly published literature in the field.

In a book with the depth and breadth of Psychiatry, a number of editorial decisions had to be made regarding the inclusion or omission of specific material and how information should be organized and presented. To make Psychiatry “user friendly,” we have liberally used tables, charts, and illustrations to highlight key information. For example, clinical vignettes throughout the text are highlighted by a standard graphic element. Thus, an individual wishing to focus on the clinical aspects of psychiatry can do so by searching for the clinical vignettes located throughout the book. Whenever possible, we have used diagnostic and treatment decision trees to help both the novice and the experienced clinician arrive at a more rational method for making these clinical decisions. This reinforces the emphasis on clinical management issues in the section on
For hundreds of years, modern medicine has struggled to understand the interactions of the mind and body. A review of medical history of the last several centuries reveals that this problem was resolved in Western cultures by splitting the functions of the mind and the body. In recent decades, as a result of substantial research advances, this approach has begun to change. We come down clearly on the side of those who believe that such a split not only is undesirable but also does not reflect the true state of human life. Thus, we have made every possible attempt to integrate the information in this book within a biopsychosocial framework. Along with the emergence of neurobiology as a discipline, social psychiatry has evolved in recent decades as we have become more aware that the unique social and cultural background of each individual patient can influence the development and manifestations of illness, the physician-patient relationship, the response to treatment, and long-term management. Rather than relegate these issues to a specific chapter, we have chosen to integrate them throughout the entire book.

We envision that *Psychiatry* will have multiple uses. Clinicians at all levels of experience, from the medical student who wishes a quick review to the experienced clinician who wishes to delve into a particular psychiatric topic, will find that the structure and format of *Psychiatry* are conducive to meeting a variety of needs. Health care professionals in other fields of medicine who must recognize or treat psychiatric illness will also find much useful information here.

*Psychiatry* is the centerpiece of a series of works that will provide a comprehensive program for psychiatric learning. Companion texts will include a review and self-assessment referenced to *Psychiatry*, a behavioral sciences text for medical students that offers a distillation of key information that every physician in training must have, a pocket guide for ready reference in the clinical setting, and a book that focuses on the pharmacological aspects of psychiatric practice.

*Psychiatry* has been enriched by the contributions of literally hundreds of individuals. Our section editors did an outstanding job both in helping to select chapter authors and in developing the specific format and content of each section. Although editing a multiple-authored text such as *Psychiatry* is a complex and challenging task, our work was made considerably easier by the uniform excellence of our authors’ chapters and the diligence of our section editors in helping to mold first drafts into final products.

In addition to the scholarly aspects of the text, a work of this magnitude cannot be produced without the strong and ongoing support of a large number of individuals responsible for its production. Each of us has had experience in editing other books, but never have we received such sustained and outstanding editorial support. Particular thanks go to Judy Fletcher, who approached Allan Tasman with her original idea for this book. Judy’s accomplishments include not only successfully nurturing *Psychiatry* to fruition but also nurturing a baby daughter in the process. Judy was unfailingly available and helpful to us. Once the material reached the production stage, Les Hoeltzel, our developmental editor, did yeoman’s work. A master of persuasion, Les shepherded the manuscripts through the production process into a finished textbook. Joanie Milnes, in Les’ office, was consistently helpful and available.

Joan Lucas, in Allan Tasman’s office, deserves our everlasting gratitude for her ability to keep track of hundreds of details and thousands of pages of manuscript and to maintain contact among three editors, seven section editors, and more than 100 chapter authors. Her level of organizational skill is matched only by her diplomatic skill in teasing delayed material from reluctant authors. Judy Yanko, in Jerry Kay’s office, was also invaluable in sustaining our efforts. Maureen Ward, in Jeff Lieberman’s office in New York (before he moved to North Carolina), efficiently and patiently coaxed, catalogued, and transferred dozens of chapters during the course of this project.

Most important, this work could not have been accomplished without strong support and encouragement from our families. With understanding and good humor, our spouses and children endured many hours of evening and weekend time devoted to work on *Psychiatry* that in other circumstances would have been devoted to them.

ALLAN TASMAN, MD
JERALD KAY, MD
JEFFREY A. LIEBERMAN, MD
When we undertook the development of the first edition of Psychiatry, our goal was to produce the highest quality textbook of general psychiatry; one that would provide a valuable resource to mental health clinicians, trainees, and students in a scholarly yet creative and accessible format. We have been very gratified by the response to the first edition of this textbook from colleagues, students, and reviewers who have found our book to be a comprehensive and valued reference. As we have watched the book’s acceptance in both academic and clinical psychiatry settings, we have also been mindful of the march of science and the expanding knowledge base in our field. Thus, it became clear to us that between the successful reception of the first edition and the accelerated rate of scientific progress in psychiatry and neuroscience, it was time to plan for a second edition.

While this new edition maintains the same basic structure and philosophy on which the first edition was based, some significant changes have also been made. We maintain the emphasis on approaching the patient, and his/her diagnosis and treatment, from a biopsychosocial perspective, informed by an understanding of normal and pathological development, and complemented by an in-depth knowledge of the structure and function of the central nervous system. Moreover, we retain the focus on the centrality of the doctor–patient relationship in understanding our patients.

Because global scientific and medical communications are ever improving, we have expanded the book’s scope to make it more international in its perspective. We have increased the emphasis on understanding how the cultural and ethnic background of our patients influences human development, disease expression and the nature of the doctor–patient relationship, and we have expanded our discussion of diagnostic and treatment variations around the world. Such additions are reflected by contributions from new authors and editors, with additional chapters, and new material within chapters. Additionally, the second edition contains 20 new chapters and extensive revisions of all chapters, reflecting all relevant clinical and scientific developments that have occurred since the first edition. With the benefit of an accelerated production process, we have been able to include many of the most important advances and references from 2002.

Once again, Psychiatry has benefited from the contributions of an incredibly scholarly and eminent group of authors and editors. The daunting task of producing this work was facilitated by their diligence and scholarship.

The publication of the second edition marks a new relationship with John Wiley & Sons, Ltd. Many individuals at Wiley have devoted themselves to helping produce and market the highest quality work, in particular Charlotte Brabants, Layla Paggetti, Amelia Bennett, and Andrew Spong. Charlotte, our editor, has been enthusiastic about the potential for the second edition since our first conversation, and that enthusiasm, paired with her skill and perseverance, has played an important role in bringing this work to fruition. Amelia has done sterling work to ensure that this edition has been produced with the highest standards of quality and on schedule. Just as with the first edition, we have also had tremendous help in our home institutions. Joan Lucas in Allan Tasman’s office, Edward Depp in Jerry Kay’s office, and Janice Linn and Tim McElwee in Jeff Lieberman’s office all deserve credit for the quality and timeliness of this edition.

As before, this work could not have been completed without strong support and encouragement from our families. Though most of our children are now away from home, those remaining at home, and our spouses, deserve our thanks for their understanding as we took time to produce this work, time which otherwise would have been devoted to them.

ALLAN TASMAN, MD
JERALD KAY, MD
JEFFREY A. LIEBERMAN, MD
Figure 15–1 Location and relationship of the human hippocampus and amygdala. As described in the text, the hippocampus has an important role in memory formation and stress modulation. Hippocampal dysfunction is implicated in numerous psychiatric disorders, including major depressive disorder, PTSD, schizophrenia, and dementia. The amygdala, which we do not treat in detail in this chapter but which is discussed at length elsewhere in this textbook, is involved in both negative and positive emotion, and is implicated clinically in mood and anxiety disorders.

Figure 15–2 Anatomy of the human dorsal and ventral striatum, which are major input nuclei of the basal ganglia. As described in the text, the ventral striatum is implicated in reward and reinforced learning; dysregulation of ventral striatal function is implicated in addiction, schizophrenia, depression, and other disorders. The dorsal striatum functions both in motor control and in the acquisition and performance of automated learned behaviors, including habits; its dysfunction is implicated in OCD, drug addiction, and other disorders.
Figure 15–3  Neuroanatomy of the frontal cortical structures described in the text. The rostral anterior cingulate cortex (rACC) and ventromedial prefrontal cortex (vmPFC) have roles in emotion regulation, especially in the absence of an explicit attempt to regulate emotional processing. The dorsolateral prefrontal cortex (DLPFC) is critical for working memory and executive function and for deliberate forms of emotion regulation. As described in the text, functional perturbation of these structures and of their functional interrelationships is implicated in numerous psychiatric disorders, including schizophrenia, PTSD, and depression.

Figure 19–2  Gray matter maturation for healthy and schizophrenic children and adolescents. Comparison of the patterns of cortical gray matter (GM) loss in childhood onset schizophrenia (COS) (between ages 12 to 16) to that seen in normal cortical maturation (between ages 4 to 22). A. Right lateral view of the dynamic sequences of cortical GM maturation in healthy children between ages 4 and 22 (n=13, 54 scans; upper panel) resampled every 2 years. Scale bar shows GM amount at each of the 65,536 cortical points across the entire cortex represented using a color scale (Red to Pink—More GM, Blue—GM Loss). Cortical GM maturation appears to progress in a “back to front” (parieto-temporal) manner (Gogtay et al. 2004). B. Right lateral view of the dynamic sequence of cortical GM maturation in COS between ages 12 to 16 compared with ages and sex matched healthy controls (n=12, 36 scans in each group), where children are resampled every 2 years. Dynamic maps represent p-values for the difference in GM amount between COS and controls at each of the 65,536 cortical points, and p-values are represented using a color scale (that is P(>0.00002)). Cortical GM loss in COS also appears to follow in a “back to front” direction on the lateral surface, thus suggesting that the COS pattern is an exaggeration of the normal GM maturation (Thompson et al. 2001). Data on childhood onset schizophrenia only, ages 12 to 16. International Psychopharmacology Algorithm Project (IPAP) Schizophrenia Algorithm (updated 17 March 2006). Available online at: www.ipap.org

Plate II
Plate III

Sagittal section through a representative rodent brain illustrating the pathways and receptor systems implicated in the acute reinforcing actions of drugs of abuse. Cocaine and amphetamines activate the release of dopamine in the nucleus accumbens and amygdala via direct actions on dopamine terminals. Opioids activate opioid receptors in the ventral tegmental area, nucleus accumbens, and amygdala via direct actions on interneurons. Opioids facilitate the release of dopamine in the nucleus accumbens via an action either in the ventral tegmental area or the nucleus accumbens, but also are hypothesized to activate the elements independent of the dopamine system. Alcohol activates γ-aminobutyric acid-A (GABA_A) receptors in the ventral tegmental area, nucleus accumbens, and amygdala via either direct actions at the GABA_A receptor or through indirect release of GABA. Alcohol is hypothesized to facilitate the release of opioid peptides in the ventral tegmental area, nucleus accumbens, and central nucleus of the amygdala. Alcohol facilitates the release of dopamine in the nucleus accumbens via an action either in the ventral tegmental area or the nucleus accumbens. Nicotine activates nicotinic acetylcholine receptors in the ventral tegmental area, nucleus accumbens, and amygdala, either directly or indirectly, via actions on interneurons. Nicotine also may activate opioid peptide release in the nucleus accumbens or amygdala independent of the dopamine system. Cannabinoids activate cannabinoid CB1 receptors in the ventral tegmental area, nucleus accumbens, and amygdala via direct actions on interneurons. Cannabinoids facilitate the release of dopamine in the nucleus accumbens via an action either in the ventral tegmental area or the nucleus accumbens, but also are hypothesized to activate the elements independent of the dopamine system. Endogenous cannabinoids may interact with postsynaptic elements in the nucleus accumbens involving dopamine and/or opioid peptide systems. The blue arrows represent the interactions within the extended amygdala system hypothesized to have a key role in psychostimulant reinforcement. AC: anterior commissure; AMG: amygdala; ARC: arcuate nucleus; BNST: bed nucleus of the stria terminalis; Cer: cerebellum; C-P: caudate-putamen; DMT: dorsomedial thalamus; FC: frontal cortex; Hippo: hippocampus; IF: inferior colliculus; LC: locus coeruleus; LH: lateral hypothalamus; N Acc.: nucleus accumbens; OT: olfactory tract; PAG: periaqueductal gray; RPN: reticular pontine nucleus; SC: superior colliculus; SNr: substantia nigra pars reticulata; VP: ventral pallidum; VTA: ventral tegmental area. (Taken with permission from Koob 2005.)
Plate IV

**Figure 22–10** Molecular mechanisms of neuroadaptation. Cocaine and amphetamines, as indirect sympathomimetics, stimulate the release of dopamine which acts at G protein-coupled receptors, specifically D1, D2, D3, D4, and D5. These receptors modulate the levels of second-messengers like cyclic adenosine monophosphate (cAMP) and Ca2+, which in turn regulate the activity of protein kinase transducers. Such protein kinases affect the functions of proteins located in the cytoplasm, plasma membrane, and nucleus. Among membrane proteins affected are ligand-gated and voltage-gated ion channels (VGCC). Gi and Go proteins also can regulate potassium and calcium channels directly through their βγ subunits. Protein kinase transduction pathways also affect the activities of transcription factors. Some of these factors, like cAMP response element binding protein (CREB), are regulated posttranslationally by phosphorylation; others, like Fox, are regulated transcriptionally; still others, like Jun, are regulated both posttranslationally and/or transcriptionally. While membrane and cytoplasmic changes may be only local (e.g., dendritic domains or synaptic boutons), changes in the activity of transcription factors may result in long-term functional changes. These may include changes in gene expression of proteins involved in signal transduction and/or neurotransmission, resulting in altered neuronal responses. For example, chronic exposure to psychostimulants has been reported to increase the levels of protein kinase A (PKA) and adenylyl cyclase in the nucleus accumbens and to decrease the levels of Gαi. Chronic exposure to psychostimulants also alters the expression of transcription factors themselves. CREB expression, for instance, is depressed in the nucleus accumbens by chronic cocaine treatment. Chronic cocaine induces a transition from Fox induction to the induction of the much longer lasting Fox-related antigens (Fras) such as ΔFosB. Opioids, by acting on neurotransmitter systems, affect the phenotypic and functional properties of neurons through the general mechanisms outlined in the diagram. Examples of ligand-gated ion channels such as the γ-aminobutyric acid-A (GABA_A) and glutamate N-methyl-D-aspartate (NMDA) receptor (NMR) and G protein-coupled receptors such as opioid, dopamine (DA), or the cannabinoid CB receptors, among others, are shown. The latter also is activated by endogenous cannabinoids such as anandamide. These receptors modulate the levels of second messengers such as cAMP and Ca2+, which in turn regulate the activity of protein kinase transducers. Such protein kinases affect the functions of proteins located in the nucleus.
Plate V

Figure 22–8 \(^{18}F\)N-methylspiroperidol images in a normal control and in a cocaine abuser tested 1 month and 4 months after last cocaine use. The images correspond to the four sequential planes where the basal ganglia are located. The color scale has been normalized to the injected dose. Notice the lower uptake of the tracer in the cocaine abuser compared to the normal control. Notice also the persistence of the decreased uptake even after 4 months of cocaine discontinuation. BNL: Brookhaven National Laboratory; SUNY: State University of New York. (Taken with permission from John Wiley and Sons Inc. 1993.)

Figure 22–9 (Continued from facing page)  

cytoplasm, plasma membrane, and nucleus. Among membrane proteins affected are ligand-gated and VGCCs. Alcohol, for instance, has been proposed to affect the GABA\(_A\) response via protein kinase C (PKC) phosphorylation. \(G\_i\) and \(G\_o\) proteins also can regulate potassium and calcium channels directly through their \(\beta\gamma\) subunits. Chronic exposure to alcohol has been reported to increase levels of protein kinase \(A\) and adenylyl cyclase in the nucleus accumbens and to decrease the levels of \(G\_i\). Moreover, chronic ethanol induces differential changes in subunit composition in the GABA\(_A\) and glutamate inotropic receptors and increases the expression of VGCCs. Chronic exposure to alcohol also alters the expression of transcription factors themselves. CREB expression, for instance, is increased in the nucleus accumbens and decreased in the amygdala by chronic alcohol treatment. Chronic alcohol induces a transition from Fos induction to the induction of the longer lasting FRAs. Nicotine acts directly on ligand-gated ion channels. These receptors modulate the levels of Ca\(^{2+}\), which in turn regulate the activity of protein kinase transducers. Chronic exposure to nicotine has been reported to increase the levels of protein kinase \(A\) in the nucleus accumbens. Chronic exposure to nicotine also alters the expression of transcription factors themselves. CREB expression, for instance, is depressed in the amygdala and prefrontal cortex and increased in the nucleus accumbens and ventral tegmental area. \(Δ^9\)-tetrahydrocannabinol, by acting on neurotransmitter systems, affects the phenotypic and functional properties of neurons through the general mechanisms outlined in the diagram. Cannabinoids act on a G protein-coupled receptor, the cannabinoid CB\(_1\) receptor. The CB\(_1\) receptor also is activated by endogenous cannabinoids such as anandamide. This receptor modulates (inhibits) the levels of second messengers like cAMP and Ca\(^{2+}\), which in turn regulates the activity of protein kinase transducers. Chronic exposure to \(Δ^9\)-tetrahydrocannabinol also alters the expression of transcription factors themselves. PLC\(_B\), phospholipase \(C\); IP\(_3\), inositol triphosphate; CaMK, calmodulin-dependent protein kinase; PI3K, phosphatidylinositol-3-kinase; MAPK, mitogen-activated protein kinase; ELK-1, endothelin-1-specific-like gene-1 transcription factor. (Modified with permission from Koob et al. 1998.)

Plate V
Figure 25–4  Cumulative lifetime probability of treatment contact for mood disorders from year of onset*. *Significance of differences among curves: $\chi^2 = 0.7$, $p = .718$. *Based on survival analysis. The projected proportions of cases that will eventually make treatment contact for each disorder are estimated to be: major depressive disorder (MDE), 88.1%; dysthymia (DYS), 94.2%; bipolar disorder (BPD) I and II, 90.2%.

Figure 25–5  Cumulative lifetime probability of treatment contact for anxiety disorders from year of onset*. *Significance of differences among curves: $\chi^2 = 242.4$, $p < .001$. *Based on survival analysis. The projected proportions of cases that will eventually make treatment contact for each disorder are estimated to be: panic disorder (PD), 95.3%; agoraphobia without panic (AG), 66.5%; specific phobia (SP), 50.1%; social phobia (SoP), 74.0%; generalized anxiety disorder (GAD), 86.1%; posttraumatic stress disorder (PTSD), 65.3%; separation anxiety disorder (SAD), 27.3%.
Figure 25–6 Cumulative lifetime probability of treatment contact for impulse-control disorders from year of onset*. *Significance of differences among curves: $\chi^2 = 6.0, p = .050$. *Based on survival analysis. The projected proportions of cases that will eventually make treatment contact for each disorder are estimated to be: attention-deficit/hyperactivity disorder (ADHD), 51.8%; oppositional defiant disorder (ODD), 33.9%; intermittent explosive disorder (IED), 50.4%.

Figure 25–7 Cumulative lifetime probability of treatment contact for substance disorders from year of onset*. *Significance of differences among curves: $\chi^2 = 44.8, p < .001$. *Based on survival analysis. The projected proportions of cases that will eventually make treatment contact for each disorder are estimated to be: alcohol abuse (AA), 52.7%; alcohol dependence (AD), 69.8%; drug abuse (DA), 57.0%; drug dependence (DD), 76.9%.
Figure 26–1 Some of the brain regions and cognitive processes involved in attentional deployment and executive function. Regions in red are targeted by regions in yellow, according to the theory of Miller and Cohen (2001), as well as others. Note that regions that are not shown would not be visible from the surface because they are located subcortically. FEF, frontal eye fields; TPJ, temporal parietal junction; IFG, inferior frontal gyrus; DLPFC, dorsolateral prefrontal cortex; ACC, anterior cingulate cortex; SC, sensory cortices.

Figure 26–2 Some of the brain regions and cognitive processes involved in the encoding, binding, and retrieval of explicit and implicit memory. IFG, inferior frontal gyrus; HIP, hippocampus; AM, amygdala; SOC, superior occipital cortex.
Figure 26–3 Some of the brain regions and cognitive processes involved in uniquely social cognition. Regions in red are predominantly involved in shared representations, and regions in yellow are predominantly involved in cognitive attribution and perspective taking, though this is by no means a definitive division of labor. Note that the anterior insula, while presented on the surface of the cortex, is underneath the cortex. MPFC, medial prefrontal cortex; PCC, posterior cingulate cortex; TPJ, temporoparietal junction; STS, superior temporal sulcus; ACC, anterior cingulate cortex; AI, anterior insula; PMC, premotor cortex.

Figure 33–3 Diffusion tensor tractography image demonstrating major white matter tracts in the human brain. © Wallace-Kettering Neuroscience Institute
Figure 33–6 Illustration of the methodology for PET activation studies using blood flow tracers such as $^{15}$O-carbon dioxide or $^{15}$O-water. A series of scans are acquired in activated and control states and are subtracted to produce a different image. A statistical test is applied to the data to determine which changes in the difference image are statistically significant. This example shows the robust response to a hemifield stimulation of the visual system with a reversing checkerboard pattern using $^{15}$O-water as the tracer. The activated area in the visual cortex can clearly be seen, even prior to subtraction. © Academic Press

Figure 33–7 Serial axial HMPAO SPECT images from an individual with Binswanger's disease. HMPAO SPECT measures cerebral blood flow which is tightly coupled to neuronal activity. Note that there is generalized decrease in cortical activity compared with cerebellum. Additionally, small marked focal defects are seen in the cortex (arrowheads). © Mosby

Plate X
Figure 33–8 fMRI activation study where subjects were given either intravenous cocaine or saline at different times. When the saline condition is subtracted from the cocaine condition (see Figure 33–6 for activation study overview), statistically significant activation associated with administration of cocaine was demonstrated in regions associated with the reward circuitry of the brain. Also note that when this study is conducted using a 3 Tesla (unit used to quantitate the strength of a magnetic field) MR scanner, the findings are much more robust than when using a less powerful 1.5 Tesla MR scanner.
Molecular imaging. $^{18}$F-Fallypride is a dopamine receptor radioligand with high affinity for D$_2$ and D$_3$ dopamine receptors. The highest concentration of binding is seen in the dorsal striatum (caudate and putamen), followed by the thalamus and temporal and prefrontal cortices.
Regions of increased brain metabolic activity using [18F] - FDG-PET during psilocybin

Resting state

Psilocybin

Figure 60–5 18F-deoxyglucose positron emission tomography of health volunteers before and after the administration of psilocybin. In addition to a global increase in brain metabolic activity, note the increase in activation in the anterior cingulated and lateral and medial frontal cortex, and the medial temporal cortex. Metabolic activation correlated with the intensity of subjective symptoms. Figure 60–6 a–f. Drawings of hallucinations by patients with hallucinogen persisting perception disorder. These drawings of visual symptoms were made by actively symptomatic patients in a drug-free condition. Such imagery occurred to the patients on a daily basis. No patient was psychotic. Each knew that the visual disturbances were “not real.” Image (A) the perception of flashes of light; (B) seeing countless dots moving in the air; (C) geometric shapes moving in swirling pattern; (D) pareidolia, in which the patient saw faces in the veneer of wood; (E) the trailing of afterimages as an arrow moved through the patient’s visual field; (F) difficulty reading caused by moving afterimages of letters appearing on the paper suggesting an acquired dyslexia.
Figure 60–8  Increased EEG coherence in HPPD subjects between occipital electrodes. Thirty-eight actively symptomatic HPPD subjects and 33 controls were tested for electrical coherence, a measure of cortical coupling, between adjacent electrode pairs in the eyes open and closed states. The figure is a T-statistics Significance Probability Map of group differences in t-scores derived from mean coherence values at each pixel. Coherence is measured from the OZ electrode at 6 Hz. The view is top down, with the nose at the top. Increased coherence, denoted by a color gray scale, is increased occipitally denoted in white, and in the right temporal electrodes, in the HPPD sample with eyes closed, when visual hallucinations are reported to be more vivid. A global reduction in coherence is seen in HPPD between occipital and more distant electrodes, when compared to controls. (See the original publication for actual color values.) Approaches to the Patient
Listening: The Key Skill in Psychiatry

It was Freud who raised the technique of psychiatric examination—listening—to an expert level unexplored in earlier eras. Binswanger (1963) said of the period prior to Freud: “psychiatric ‘auscultation’ and ‘percussion’ was performed as if through the patient’s shirt with so much of his essence remaining covered or muffled that layers of meaning remained unpeeled away or unexamined.”

This metaphor and parallel to the cardiac examination is worth considering as we ask if listening will remain a central part of psychiatric examination. The explosion of biomedical knowledge has radically altered our evolving view and practice of the doctor–patient relationship. Physicians of an earlier generation were taught that the diagnosis is made at the bedside; that is, the history and physical examination are paramount. Laboratory and imaging examinations were seen as confirmatory exercises. As our technologies have blossomed, the bedside and/or consultation room examinations have evolved into the method whereby the physician determines what tests to run, and the tests are often viewed as making the diagnosis. A cardiologist colleague expresses the opinion that, given the growing availability of noninvasive tests—echocardiograms, for example—he is not sure that this is a bad thing (Hillis 2001, personal communication). This alteration of the core doctor–patient relationship has been exacerbated by the advent of the electronic medical record. It is not unusual for the patient to carry on a conversation with his/her physician as the doctor scans a computer screen.

So can one imagine a time in the not-too-distant future when the psychiatrist’s task will be to identify that the patient is psychotic and then order some benign brain imaging study that will identify the patient’s exact disorder?

Perhaps so, but will that obviate the need for the psychiatrist’s special kind of listening? Indeed, there are those who claim that psychiatrists should no longer be considered experts in the doctor–patient relationship (expertise derived from unique training in listening skills) but experts in the brain (Nestler 1999, personal communication). On the other hand, the psychiatrist will always be charged with finding ways to relate effectively to those who cannot relate to anyone else. The treatment of individuals whose illnesses are expressed through disturbances of thinking, feeling, perceiving, and behaving will always demand special expertise in establishing a therapeutic relationship—that is dependent on special expertise in listening. As if to underline this point, teaching listening continues to be prominently emphasized in many psychiatry training programs irrespective of their emphases (Nuzzarello and Birndorf 2004). And the need to be listened to has led to the development of websites offering listening and training in the art (Yen 2006, Parekh 2006). Further, the field continues to turn out books on psychiatric interviewing and the art of listening regularly (Poole and Higgo 2006, Mackinnon et al. 2006).

Clinical Vignette 1

A 28-year-old white married man suffering from paranoid schizophrenia and obsessive-compulsive disorder did extremely well in the hospital, where his medication had been changed to clozapine with good effects. But he rapidly deteriorated on his return home. It was clear that the ward milieu had been a crucial part of his improvement, so partial hospitalization was recommended. The patient demurred, saying that he did not want to be a “burden.” The psychiatrist explored this with the patient and his wife. Beyond the obvious “burdens” of cost and travel arrangements, the psychiatrist detected the patient’s striving to be autonomously responsible for handling his illness. By conveying a deep respect for that wish, and then educating the already insightful patient about the realities of “bearing schizophrenia,” the psychiatrist was able to help the patient accept the needed level of care.

Traditionally, this kind of listening has been called “listening with the third ear” (Reik 1954). Other efforts to label this difficult-to-describe process have developed other terms: the interpretive stance, interpersonal sensitivity, the narrative perspective (McHugh and Slavney 1986). All psychiatrists, regardless of theoretical stance, must learn this skill and struggle with how it is to be defined and taught. Biological or phenomenological psychiatrists listen for subtle expressions of symptomatology; cognitive–behavioral psychiatrists listen for distortions, irrational assumptions,
or global inferences; psychodynamic psychiatrists listen for hints at unconscious conflicts; behaviorists listen for covert patterns of anxiety and stimulus associations; family systems psychiatrists listen for hidden family myths and structures. Another way to conceptualize this process, drawn from the empirical literature (Truax 1963), involves nonspecific factors crucial to outcome in all forms of psychiatric treatment: empathy, noncontingent positive regard, and therapist authenticity.

However one labels and defines the process of therapeutic listening, it requires sensitivity to the storyteller, integrating a patient orientation with a disease focus. The listener’s intent is to uncover what is wrong, to put a label on it. Simultaneously, the listener is on a journey to discover who the patient is, employing tools of asking, looking, testing, and clarifying. The patient is invited to collaborate as an active informer. Listening work takes time, concentration, imagination, a sense of humor, and an attitude that places the patient as hero of his or her own life story. Key listening skills are listed in Table 1–1.

The enduring art of psychiatry involves guiding the depressed patient, for example, to tell his or her story of loss in addition to having him or her name, describe, and quantify symptoms of depression. The listener, in hearing the story, experiences the world and the patient from the patient’s point of view, helping carry the burden of loss, lightening and transforming the load. In hearing the sufferer, the depression itself is lifted and relieved. Listening is healing as well as diagnostic. If done well, the listener becomes a better disease diagnostician. The best listeners hear both the patient and the disease clearly, and regard every encounter as potentially therapeutic.

### The Primary Tools: Words, Analogies, Metaphors, Similes, and Symbols

To listen and understand requires that the language used between speaker and hearer be shared—that meanings of words and phrases are commonly held. Common language is the predominant factor in the social organization of humanity (Chomsky 1972) and is probably the single most important key to the establishment of an active listener/engaged storyteller dyad. The Sapir–Whorf hypothesis suggests that what we are able to think is limited/determined by the language in which we are working (Carroll and Whorf 1956, Sapir 2000). More recent evolutionary thinking about language suggests that it is a crucial mechanism for maintaining social organization (Dunbar 2004). That is, what people are disposed to speak of in normal ordinary speech are their relationships and their implications.

### Clinical Vignette 2

A psychiatric consultant was asked to see a 48-year-old man on a coronary care unit for chest pain deemed “functional” by the cardiologist who had asked the patient if his chest pain was “crushing.” The patient said no. A variety of other routine tests were also negative. The psychiatrist asked the patient to describe his pain. He said, “It’s like a truck sitting on my chest, squeezing it down.” The psychiatrist promptly recommended additional tests that confirmed the diagnosis of myocardial infarction. The cardiologist may have been tempted to label the patient a “bad historian,” but the most likely culprit of this potentially fatal misunderstanding lies in the connotative meanings each ascribed to the word “crushing” or to other variances in metaphorical communication.

### Clinical Vignette 3

A psychiatrist had been treating a 35-year-old man with a narcissistic personality and dysthymic disorder for 2 years. Given the brutality and deprivation of the patient’s childhood, the clinician was persistently puzzled by the patient’s remarkable psychological strengths. He possessed capacities for empathy, self-observation, and modulation of intense rage that were unusual, given his background. During a session the patient, in telling a childhood story, began, “When I was a little fella . . .” It struck the psychiatrist that the patient always said “little fella” when referring to himself as a boy, and that this was fairly distinctive phrasing. Almost all other patients will say, “When I was young a kid a girl (boy)/in school,” designate an age, etc. On inquiry about this, the patient immediately identified “The Andy Griffith Show” as the source. This revealed a secret identification with the characters of the TV show, and a model that said to a young boy, “There are other ways to be a man than what you see around you.” Making this long-standing covert identification fully conscious was transformative for the patient.

Patients are storytellers primarily about their important relationships, who have the hope of being heard and understood (Edelsohn 1993). Their hearers are physicians who expect to listen actively and to be with the patient at a new level of understanding. Because all human beings listen to many different people every day, we tend to think of listening as an automatic ongoing process, yet this sort of active listening remains one of the central skills in clinical psychiatry. It underpins all other skills in diagnosis, alliance building, and communication. In all medical examinations, the patient is telling a story only she or he has experienced. The physician must glean the salient information and then use it in
appropriate ways. Inevitably, even when language is common, there are differences in meaning, based on differences in gender, age, culture, religion, socioeconomic class (SES), race, region of upbringing, nationality, and mother tongue, as well as idiosyncrasies of individual history. These differences are particularly important to keep in mind in the use of analogies, similes, and metaphors. Figures of speech, in which one thing is held representational of another, are very important windows to the inner world of the patient. Differences in meanings attached to figures of speech can complicate their use. In psychodynamic assessment and psychotherapeutic treatment, these subtleties of language become the self-conscious focus of the psychiatrist, yet failure to hear such idiosyncratic distinctions can affect simple medical diagnosis as well.

In psychotherapy, the special meanings of words become the central focus of the treatment.

**How Does One Hear Words in This Way?**

The preceding clinical vignettes, once described, sound straightforward. Yet, to listen in this way the clinician must acquire specific yet challenging skills and attitudes. It is extremely difficult to put into words the listening processes embodied in these examples and those to follow, yet that is what this chapter must attempt to do.

Students, when observing experienced psychiatrists interviewing patients, often express a sense of wonder such as: "How did she know to ask that?" "Why did the patient open up with him but not with me?" "What made the diagnosis so clear in that interview and not in all the others?" The student may respond with a sense of awe, a feeling of ineptitude and doubt, or even a reaction of disparagement that the process seems so indefinable and inexact. The key is the clinician's ability to listen. Without a refined capacity to hear deeply, the chapters on other aspects of interviewing in this textbook are of little use. But it is neither mystical nor magical nor indefinable; such skills are the product of hard work, much thought, intense supervision, and extensive in-depth exposure to many different kinds of patients.

Psychiatrists, more than any other physicians, must simultaneously listen symptomatically and narratively/experientially. They must also have access to a variety of theoretical perspectives that inform their listening, including behavioral, interpersonal, cognitive, sociocultural, and systems theories. Symptomatic listening is traditional medical history taking in which the focus is on the presence or absence of a particular symptom, the most overt content level of an interview. Narrative-experiential listening is based on the idea that all humans are constantly interpreting their experiences, attributing meaning to them, and weaving a story of their lives with themselves as the central character. This process goes on continuously, both consciously and unconsciously, as a running conversation within each of us. The conversation is between parts of ourselves and between ourselves and what Freud called “internalized objects,” important people in our lives whose images, sayings, and attitudes become permanently laid down in our memories. This conversation and commentary on our lives includes personal history, repetitive behaviors, learned assumptions about the world, and interpersonal roles. These are, in turn, the products of individual background, cultural norms and values, national identifications, spiritual meanings, and family system forces. In diagnosing most medical ailments, attention to the complex meanings of words is not crucial (Clinical Vignette 2 is an exception); in psychiatry it is central.

**Clinical Vignette 4**

A 46-year-old man was referred to a psychiatrist from a drug study. The patient had both major depression and dysthymic disorder since a business failure 2 years earlier. His primary symptoms were increased sleep, decreased mood, libido, energy, and interests. After no improvement during the “blind” portion of the study, he had continued to show little response once the code was broken, and he was treated with two different active antidepressant medications. He was referred for psychotherapy and further antidepressant trials. The therapy progressed slowly with only episodic improvement. One day, the patient reported that his wife had been teasing him about how, during his afternoon nap, his snoring could be heard over the noise of a vacuum cleaner. The psychiatrist immediately asked additional questions, eventually obtained sleep polysonography, and, after appropriate treatment for sleep apnea, the patient’s depression improved dramatically.

Three factors were present that enabled the psychiatrist in this vignette to identify an unusual diagnosis that had been missed by three other excellent clinicians, using detailed structured interviews that, extremely inclusive in their symptom reviews. First, the psychiatrist had to have available in mind many symptoms and syndromes. Second, he was in a curious mode. In fact, this clinician had a gnawing sense that something was missing in his understanding of the patient. There is a saying in American medicine designed to focus students on the need to consider common illnesses first: when you hear hoofbeats don’t look for zebras. This psychiatrist’s mind was open to seeing a “zebra” despite the ongoing assumption that the weekly “hoofbeats” represented the everyday “horse” of clinical depression. Finally, he heard the patient’s story in multiple, flexible ways, including the possibility that a symptom may be embedded in it, so that a match could be noticed between a detail of the story and a symptom. Eureka! The zebra could be seen though it had been there weekly for months.

Looking back at Clinical Vignette 3, we see the same phenomenon of a detail leaping out as a significant piece of missing information that dramatically influences the treatment process. This requires a cognitive template (symptoms and syndromes; developmental, systemic, and personality theories; awareness of cultural perspectives), a searching inquisitive stance, and flexible processing of the data. If one is able to internalize the skills listed in Table 1–1, the listener begins to automatically hear multiple meanings in the words.

**Listening as More Than Hearing**

Listening and hearing are often equated. However, listening involves not only hearing and understanding the speaker’s words, but attending to inflection, metaphor, imagery, sequence of associations, and interesting linguistic selections. It also involves seeing—movement, gestures, facial expressions, subtle changes in these—and constantly comparing what is said with what is seen, looking for dissonances, and comparing what is being said and seen with what was previously communicated and observed. Further, it is essential to
be aware of what might have been said but was not, or how things might have been expressed but were not. This is where clues to idiosyncratic meanings and associations are often discovered. Sometimes, the most important meanings are embedded in what is conspicuous by its absence.

It was Darwin (1955) who first observed that there appears to be a biogrammar of primary emotions that all humans share and express in predictable, fixed action patterns. The meaning of a smile or nod of the head is universal across disparate cultures. This insight was lost until the late 1960s when several researchers from different fields (Tiger and Fox 1971, Tomkins and McCarter 1964) returned to it and provided empirical support for it. LeDoux (1996) has been a leader in identifying the neurobiological substrate for primary emotions. Brothers (1989), using this work and her own experiments with primates, developed a hypothesis about the biology of empathy based on seeing as well as hearing. Both she and Damasio (1994) have identified the amygdala and the inferior temporal lobe gyrus as the neurobiological substrate for recognition of and empathy for others and their emotional states. Further research has identified that these parts of the brain are, on the one hand, pre-determined to recognize certain gestures, facial expressions, and so on, but require effective maternal-infant interaction in order to do so (Schore 2001). More recently, the discovery of mirror neurons has added to our grasp of the neurobiology of effective listening (Harris 2007).

<tr>
<td>A 38-year-old Hispanic construction worker presented himself to a small-town emergency department in the Southwest, complaining of pain on walking, actually described in Spanish-accented English as “a little pain.” His voice was tight, his face was drawn, and his physical demeanor was burdened and hesitant. His response to the invitation to walk was met by a labored attempt to walk without favor to his painful limb. A physician could have discharged him from the emergency department with a small prescription of ibuprofen. The careful physician in the emergency department responded to the powerful visual message that he was in pain, was beaten down by it, and had suffered long before coming in. This recognition came first to the physician as an intuition that this man was somehow more sick than he made himself sound. A radiograph of the femur revealed a lytic lesion that later proved to be metastatic renal cell carcinoma. To hear the unspoken, one had to be keenly aware of the patient’s tone and how he looked, and to keep in mind, too, the cultural taboos forbidding him to give in to pain or to appear to need help.</td>
</tr>
</tbody>
</table>

All of this is synthesized in the listener as a “sense” or intuition as to what the speaker is saying at multiple levels. These mechanisms probably underlie Freud’s observation that the unconscious of the analyst listens to the unconscious of the patient. As has been implied, not only must one affirmatively “hear” all that a patient is communicating, but one must also overcome a variety of potential blocks to effective listening.

**Common Blocks to Effective Listening**

Many factors influence the ability to listen. Psychiatrists come to the patient as the product of their own life experiences. Does the listener tune in to what he or she hears in a more attentive way if the listener and the patient share characteristics? What blocks to listening (Table 1–2) are posed by differences in sex, age, religion, SES, race, culture, or nationality (Kleinman 2001, Comas-Diaz and Jacobsen 1991, Kochman 1991)? What blind spots may be induced by superficial similarities in different personal meanings attributed to the same cultural symbol? The act of listening is inevitably influenced by similarities and differences between the psychiatrist and the patient.

Would a woman have reported the snoring in Clinical Vignette 4 or might she have been too embarrassed? Would she have reported it more readily to a woman psychiatrist? What about the image in Clinical Vignette 2 of a truck sitting on one’s chest? How gender, class and culture bound is it? Would “The Andy Griffith Show,” in Clinical Vignette 3, have the same impact on a young African-American boy as on a Caucasian? How widely is “The Andy Griffith Show” available; in which cultures would that model of family structure seem relevant? Suppose the psychiatrist in Vignette 3 was not a television viewer or had arrived in the US long after the show had aired?

<td>A 45-year-old successful attorney suffering from anxiety and mild depression faced multiple sources of turmoil in his family, including with his spouse. When asked what he valued about the members of his family, he listed many aspects: his long-standing with for the “American Dream” of a white picket fence house, the importance to his career, the responsibility for seeing his children thrive, etc. What he never mentioned was his own need for intimacy and friendship from his wife. When this was pointed out, a whole new area of the patient’s life became exposed. He had never observed intimacy between his mother and father, never sought it for himself, never even imagined it as an important dimension of life.</td>
</tr>
</tbody>
</table>

It is likely that different experiences based on gender fostered this misunderstanding. How many women easily
identifies with the stereotyped role of the barnyard rooster? How many men readily identify with the role of a prostitute? These are but two examples of the myriad meanings our gender may incline us toward. Although metaphor is a powerful tool in listening to the patient, cultural barriers pose potential blocks to understanding.

Clinical Vignette 7

A female patient came to see her male psychiatrist for their biweekly session. Having just been given new duties on her job, she came in excitedly and began sharing with her therapist how happy she was to have been chosen by her male supervisor to help him with a very important project at their office. The session continued with the theme of the patient’s pride in having been recognized for her attributes, talents, and hard work. At the next session, she said that she had become embarrassed after the previous session at the thought that she had been “strutting her stuff.” The therapist reflected back to her the thought that she sounded like a rooster strutting his stuff, connecting her embarrassment at having revealed that she strove for the recognition and power of men in her company, and that she, in fact, envied the position of her supervisor. The patient objected to the comparison of a rooster, and likened it more to feeling like a woman of the streets strutting her stuff. She stated that she felt like a prostitute being used by her supervisor. The psychiatrist was off the mark by missing the opportunity to point out in the analogous way that the patient’s source of embarrassment was in being used, not so much in being envious of the male position.

Clinical Vignette 8

A 36-year-old black woman complained to her therapist (of the same language, race, and socioeconomic class) that her husband was a snake, meaning that he was no good, treacherous, a hidden danger. The therapist, understanding this commonly held definition of a snake, reflected back to the patient pertinent, supportive feedback concerning the care and caution the patient was exercising in divorce dealings with the husband.

In contrast, a 36-year-old Chinese woman, fluent in English, living in her adopted country for 15 years and assimilated to Western culture, represented her husband to her Caucasian, native-born psychiatrist as being like a dragon. The therapist, without checking on the meaning of the word “dragon” with her patient, assumed it connoted danger, one of malicious intent, and oppression. The patient, however, was using “dragon” as a metaphor for her husband—the fierce, watchful guardian of the family—in keeping with the ancient Chinese folklore in which the dragon is stationed at the gates of the lord’s castle to guard and protect it from evil and danger.

Subtle regional variations may produce similar problems in listening and understanding.

Psychiatrists discern meaning in that which they hear through filters of their own—cultural backgrounds, life experiences, feelings, the day’s events, their physical sense of themselves, nationality, sex roles, religious systems, and intrapsychic conflicts. Filters can serve as blocks or magnifiers if certain elements of what is being said resonate within the psychiatrist. When the filters block, we call it countertransference or insensitivity. When they magnify, we call it empathy or sensitivity. One may observe a theme for a long time repeated with different tones, embellishment, inflection, or context before what is meant comes to mind. The “little fella” example in Clinical Vignette 3 illustrates a message that had been communicated in many ways and times in exactly the same language before the psychiatrist “got it.” On discovering a significant meaning that had been signaled before in many ways, the psychiatrist often has the experience, “How could I have been so stupid? It’s been staring me in the face for months!”

Managed care and the manner in which national health systems are administered can alter our ability to be transforming listeners. The limitation on visits and time allotted and forms tediously filled out can be blocks to listening to the patient. With these time limits and other “third-party payer” considerations (i.e., need for a billable diagnostic code from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition [DSM-IV-TR] or the International Classification of Diseases, 10th Revision [ICD-10]), the psychiatrist, as a careful listener, must heed the external pressures influencing the approach to the patient. Many benefits packages provide coverage only for relief of symptoms, restoration of minimal function, acute problem solving, and shoring up of defenses. In various countries, health care systems have come up with a variety of constraints in efforts to deal with the cost of care. This pressures listening toward a different purpose, approximating the crisis intervention model of the emergency room or the narrow medical model. Responding to this, the psychiatrist might use checklists, inventories, and scales for objectifying the severity of illness and response to treatment: the ear is tuned only to measurable and observable signs of responses to therapy and biologic intervention.

With emphasis on here and now symptoms, will the patient be lost in the encounter? In the emergency department, emphasis is on symptom relief, assurance of capacities to keep oneself safe, restoration of minimal function, acute problem solving, and shoring up of defenses. Special attention is paid to identifying particular stressors. What can be done quickly to change stressors that threw the patient’s world into a state of disequilibrium? At least in the
emergency room the careful listener may have 3–6 hours, as opposed to 3–6 sessions with the patient in a health maintenance organization or preferred provider contract. If one is fortunate and good at being an active listener–bargainer, the seeds of change can be planted in hopes of allowing growth between emergency department visits.

Crucial Attitudes That Enable Effective Listening

The first step in developing good listening skills involves coming to grips with the importance of inner experience in psychiatric treatment and diagnosis. The DSM-IV-TR (American Psychiatric Association 1994) and ICD-10 (World Health Organization 1992) have been enormous advances in reliability and accuracy of diagnosis, but their emphasis on seemingly observable phenomena has allowed the willing user to forget the importance of inner experience even in such basic diagnoses as major depressive disorder. Consider the symptom “depressed mood most of the day” or “markedly diminished interest or pleasure” or even “decrease or increase in appetite.” These are entirely subjective symptoms. Simply reporting depression is usually not sufficient to convince a psychiatrist that a diagnosis of depression is warranted. In fact, the vast majority of psychiatric patients are so demoralized by their illnesses that they often announce depression as their first complaint. Further, there are a significant number of patients who do not acknowledge depression yet are so diagnosed. The clinician might well comment, “Sitting with him makes me feel very sad.”

The psychiatrist must listen to much more than the patient’s overt behavior. There are qualities in the communication, including the inner experiences induced in the listener that should be attended to. The experienced clinician listens to the words, watches the behavior, engages in and notices the ongoing interaction, allows himself/herself to experience his/her own inner reactions to the process, and never forgets that depression and almost all other psychiatric symptoms are largely private experiences. The behavior and interactions are useful insofar as they assist the psychiatrist in inferring the patient’s inner experience.

Therefore, to convince a clinician that a patient is depressed, not only must the patient say she/he is depressed, but the observable behavior must also convey it (sad-looking face, sighing, unexpressive intonations, etc.); the interaction with the interviewer must convey depressive qualities (sense of neediness, sadness induced in the interviewer, beseeching qualities expressed, etc.). In the absence of both of these, other diagnoses should be considered, but in the presence of such qualities, depression needs to remain in the differential diagnosis.

Even when we make statements about brain function with regard to a particular patient, we use this kind of listening, generally, by making at least two inferences. We first listen to and observe the patient and then infer some aspect of the patient’s private experience. Then, if we possess sufficient scientific knowledge, we make a second inference to a disturbance in neurochemistry, neurophysiology, or neuroanatomy. When psychiatrists prescribe antidepressant medication, they have inferred from words, moved into inner experiences, and come to a conclusion that there is likely a dysregulation of serotonin or norepinephrine in the patient’s brain.

As one moves toward treatment from diagnosis, the content of inner experience inferred may change to more varied states of feelings, needs, and conflicts, but the fundamental process of listening remains the same. The psychiatrist listens for the meaning of all behavior, to the ongoing interpersonal relationship the patient attempts to establish, and to inner experiences as well.

Despite the technological advances in medicine in general and their growing presence in psychiatry, securing or eliciting a history remains the first and central skill for all physicians. Even in the most basic of medical situations, the patient tries to communicate a set of private experiences (how does one describe the qualities of pain or discomfort?) that the physician must infer and sort into possible syndromes and diagnoses. In psychiatry, this process is multiplied, as indicated in Figure 1–1. William Styron (1990), a prizewinning novelist, went to extraordinary lengths in his eloquent attempt to convey the “searing internal mental pain” that he experienced when suffering from a major depression.

Silvano Arieti (1967) hypothesized that cognitive development produces changes over time in the inner experience of various affects. Does a person with borderline personality disorder experience “anxiety” in the same qualitative and quantitative manner in which a neurotic person does? What is the relationship between sadness and guilt and the empty experiences of depression? This perspective underlies the principle articulated in text after text on interviewing that emphasizes the importance of establishing rapport in the process of history taking. It is easy for the psychiatrist to attribute to the patient what she/he would have meant and what most people might have meant in using a particular word or phrase. The sense in the narrator that the listener is truly present, connected, and with the patient enormously enhances the accuracy of the story reported.

Words that have been used to describe this process of constant attention to and inference of inner experience by the listener include interest, empathy (Rogers 1951, Kohut 1991, Truax 1963), attentiveness, and noncontingent positive regard (Truax 1963). However, these are words that may say less than they seem to. It is the constant inquisitive awareness on the listener’s part that she/he is trying to grasp the private inner experience of the patient, and the storyteller’s sense of this stance by the psychiatrist that impels the ever more revealing process of history taking. This quality of listening produces what we call rapport, without which psychiatric histories become spotty, superficial, and even suspect. There are no bad historians, only patients who have not yet found the right listener.

In treatment, we even find empirical data to support this perspective. The two most powerful predictors of outcome in any form of psychotherapy are empathy and the therapeutic alliance (Horvath and Luborsky 1993, Greenson 1978). This has been shown again and again in study after study for dynamic therapy, cognitive therapy, behavior therapy, and even medication management (Elkin et al. 1989). This led some researchers and theorists to propose that the power of psychotherapy can be understood solely as a remoralization phenomenon based on support and empathy (Frank 1973, Omer and London 1989). The truth of this can be seen in the remarkable therapeutic success of the Clinical Management Cell of the National Institutes
of Mental Health Collaborative Study on the Treatment of Major Depression. Although the Clinical Management Cell was not as effective as the cells that included specific drugs or specific psychotherapeutic interventions, 35% of patients with moderate to severe major depressive disorder improved significantly with carefully structured supportive clinical management alone (Elkin et al. 1989).

Helpful psychiatric listening requires a complicated attitude toward control and power in the interview (see Table 1–3). The psychiatrist invites the patient/storyteller to collaborate as an active informer. He is invited, too, to question and observe himself. This attitude toward history taking remains the principal tool of general clinical medicine, even in this day of questionnaires and checklists as one arrives at the doctor’s office. The checklists may focus the interviewer but not obviate the need to explore the key symptoms. However, as Freud pointed out, these methods of active uncovering are more complex in the psychic realm. The use of the patient as a voluntary reporter requires that the investigator keep in mind the unconscious and its power over the patient and listener. Can the patient be a reliable objective witness of himself or his symptoms? Can the listener hold in mind his own set of filters, meanings, and distortions as he hears? The listener translates for himself and his patient the patient’s articulation of his experience of himself and his inner world into our definition of symptoms, syndromes, and differential diagnoses.

Objective–descriptive examiners are like detectives closing in on disease. The psychiatric detective enters the inquiry with an attitude of unknowing and suspends prior opinion. The techniques of listening invoke a wondering and a wandering with the patient. Periods of head scratching and exclamations of “I’m confused,” or “I don’t understand,” or “That’s awful!” or “Tell me more” allow the listener to follow or to point the way for the dyad. Finally, clear and precise descriptions are held up for scrutiny, with the hope that a diagnostic label or new information about the patient’s suffering and emotional pain is revealed.

It is embarking on the history taking journey together—free of judgments, opinions, criticism, or preconceived notions—that underpins rapport. Good listening requires a complex understanding of what objective truth is and how it may be found. The effective psychiatrist must eschew the traditional medical role in interviewing and tolerate a collaborative, at times meandering, direction in which control is at best shared and sometimes wholly with the patient. The psychiatrist constantly asks: What is being said? Why is it being said at this moment? What is the meaning of what is being said? In what context is all this emerging? What does that tell me about the meaning and what does it reflect about the doctor–patient relationship?

**Theoretical Perspectives on Listening**

Listening is the effort or work of placing the therapist where the patient is (“lives”). Greenson (1978) would call it “going along with”; Rogers (1951) “centering on the client.” Greenson would add that it is better to be deceived going along with the patient than to reject him/her prematurely and have the door slammed to the patient’s inner world. Personal beliefs and values are suspended in service of the discovery of the true self. Harry Stack Sullivan (1953), the father of interpersonal psychiatry, would remind us to heed those shrewd, small questions: “What is he up to?” “Where is he taking us?” Every human being has a preferred interpersonal stance, a set of relationships and transactions with which she or he is most comfortable and feels most gratified. The problem is that for most psychiatric patients they do not work well.

Beyond attitudes that enable or prevent listening there is a role for specific knowledge. It is important to develop a cognitive structure or theoretical framework and use it with rigor and discipline in the service of patients so that psychiatrists can employ more than global “feelings” or “hunches.” In striving to grasp the inner experience of any other human being, one must know what it is to be human; one must have an idea of what is inside any person. This provides a framework for understanding what the patient—who would not be a patient if he fully understood what was inside of him—is struggling to communicate. Personality theory is absolutely crucial to this process.

Whether we acknowledge it or not, every one of us has a theory of personality (in the age of porous boundaries between psychology and biology, we should speak of a psychobiological theory of human experience) that we apply in social or clinical situations. These theories become part of the template alluded to earlier that allow certain words, stories, actions, and cues from the patient to jump out with profound meaning to the psychiatrist. There is no substitute for a thorough knowledge of many theories of human functioning and a well-disciplined synthesis and internal set of rules to decide which theories to use in what situations.

Different theoretical positions offer slightly different and often complementary perspectives on listening (Table 1–4). The basic tools of therapeutic power and diagnostic acumen spring from the following:

1. **Freud’s associative methods** (Brill 1938) and ego psychology (Freud 1946), in which one listens for the associative trends and conflicts.

2. Melanie Klein’s (1975) and Harry Stack Sullivan’s (1953) object relations theory. The former discovered the story through inner world exploration and recognized the introjected persons of the past living within the patient’s mind, comprising the person’s psychic structure; the latter discovered the knowing through the interpersonal experience of the therapeutic dyad (Greenberg and Mitchell 1983).

3. Binswanger’s (1963) understanding of the condition of empathy, in which the listener gives up his or her own position for that of the storyteller.

4. Kohut’s (1991) self psychology, which emphasizes the use of vicarious introspection to reflect (mirror) back to the patient what is being understood. This mirroring engenders in the storyteller a special sense of being “found,” that is, of being known, recognized, affirmed, and heard. This feeling of being heard helps to undo the sense of aloneness so common in psychiatric patients.

Each of the great schools of psychotherapy places the psychiatrist in a somewhat different relationship to the patient. This may even be reflected in the physical placement of the therapist in relation to the patient. In a classical psychoanalytic stance, the therapist, traditionally unseen behind the patient, assumes an active, hovering attention. Existential analysts seek to experience the patient’s position and place themselves close to and facing the patient. The interpersonal psychiatrist stresses a collaborative dialogue with shared control; it stresses the need for each participant to act within that interpersonal social field.

In the object relations stance, the listener keeps in mind the “other people in the room” with him and the storyteller; the patient’s introjects, constantly part of the patient’s...
internal conversation and thus influencing the dialogue of the therapeutic dyad. In connecting with the patient, the listener is also tuned in to the fact that parts and fragments of him or her are being internalized by the patient. The listener becomes another person in the room of the patient’s life experience, within and outside the therapeutic hour. Cognitive and behavioral psychiatrists are kindly experts, listening attentively and subtly for hidden assumptions, distortions, and connections. The family systems psychiatrist sits midway among the pressures and forces emanating from each individual, seeking to affect the system so that all must adapt differently.

Referring again to Clinical Vignette 3, we can see the different theoretical models of the listening process in the discovery of the meaning of “little fella.” Freud’s model is that the psychiatrist had listened repeatedly to a specific association and inquired of its meaning. Object relations theorists would note that the clinician had discovered a previously unidentified, powerful introject. The interpersonal psychiatrist would see the shared exploration of this idiosyncratic manner of describing one’s youth; the patient had been trying to take the therapist to “The Andy Griffith Show,” attempting to induce the clinician to share the experience of imagining having Andy Griffith as a father.

Existentialists would note how the psychiatrist was changed dramatically by the patient’s repeated use of this phrase and then altered even more profoundly by the memory of Andy Griffith, “the consummate good father” in the patient’s words. The therapist could never see the patient in quite the same way again, and the patient sensed it immediately. And Kohut would note the mirroring quality of the psychiatrist’s interpreting the meaning of this important memory. This would be mirroring at its most powerful, affirming the patient’s important differences from his family, helping him to consolidate the memories. The behavioral psychiatrist would note the reciprocal inhibition that had gone on, with Andy Griffith soothing the phobic anxieties in a brutal family.

A cognitive psychiatrist would wonder whether the patient’s depression resulted from a hidden assumption that anything less than the idyllic images of television was not good enough. The family systems psychiatrist would help the patient see that he had manipulated the forces at work on him and actually changed the definition of his family.

The ways and tools of listening also change, according to the purpose, the nature of the therapeutic dyad. The ways of listening also change depending upon whether or not the psychiatrist is preoccupied or inattentive. The medical model psychiatrist listens for signs and symptoms. The analyst listens for the truth often clothed in fantasy and metaphor. The existentialist listens for feeling, and the interpersonal theorist listens for the shared experiences engendered by the interaction. Regardless of the theoretical stance and regardless of the mental tension between the medical model’s need to know symptoms and signs and the humanistic psychiatrist’s listening to know the sufferer, the essence of therapeutic listening is the suspension of judgment before any presentation of the story and the storyteller. The listener is asked to clarify and classify the inner world of the storyteller at the same time he is experiencing it—no small feat!

Using Oneself in Listening

Understanding transference and countertransference is crucial to effective listening. Tomkins, LeDoux, Damasio, and Brothers have given us a basic science, biological perspective on this process. However one defines these terms, whatever one’s theoretical stance about these issues, Harry Stack Sullivan (1969) had it right when he said that schizophrenics are more human than anything else. To know ourselves is to begin to know our patients more deeply. There are many ways to achieve this. Personal therapy is one. Ongoing life experience is another. Supervision that emphasizes one’s emotional reactions to patients is still a third. Once we have started on the road to achieving this understanding by therapy, supervision, or life experience, continued listening to our patients, who teach us about ourselves and others, becomes a lifelong method of growth.

To know oneself is to be aware that there are certain common human needs, wishes, fears, feelings, and reactions. Every person must deal in some way with attachment, dependence, authority, autonomy, selfhood, values and ideals, remembered others, work, love, hate, envy and loss. It is unlikely that the psychiatrist can comprehend the patient without his own self-awareness. Thus, Figure 1–1 should really look like Figure 1–2. The most psychotic patient in the world is still struggling with these universal human functions.

Clinical Vignette 10

An army private was brought to the emergency room in Germany by his friends, having threatened to commit suicide while holding a gun to his head. He was desperate, disorganized, impulsive, enraged, pacing, and talking almost incoherently. Gradually, primarily through his friends, the story emerged that his first sergeant had recently made a decision for the entire unit that had a particularly adverse effect on the patient. He was a fairly primitive character who relied on his wife for a sense of stability and coherence in his life. The sergeant’s decision was to send the entire unit into the field for over a month just at the time the patient’s wife was about to arrive, after a long delay, from the US. After piecing together this story, the psychiatrist said to the patient, “It’s not yourself you want to kill, it’s your first sergeant!” The patient at first giggled a little, then gradually broke out into a belly laugh that echoed throughout the emergency room. It was clear that, having recognized the true object of his anger, a coherence was restored that enabled him to feel his rage without the impulse to act on it. The psychiatrist then enlisted the friends in a plan to support the patient through the month and to arrange regular phone contact with the wife as she set up their new home in Germany. No medication was necessary. Hospitalization was averted, and a request for humanitarian dispensation, which would have compromised the patient in the eyes of both his peers and superiors, was avoided as well. And, with luck, the young man had an opportunity to grow emotionally as well.

In this case, the psychiatrist was able to connect with a patient’s inner experience in a manner that had a fairly dramatic impact on the clinical course. That is the goal of listening. The art is hearing the patient’s inner experience and then addressing it empathically, enabling the patient to
feel heard and affirmed. There are no rules about this, and at any given point in a clinical encounter there are many ways to accomplish it. There are also many ways to respond that are unhelpful and even retraumatizing. The skilled psychiatrist, just as she/he never forgets that it is the patient’s inner experience that is to be heard, also never stops struggling to find just the right words, gestures, expressions, and inflections that say to a patient, “you have been understood.” The most clever diagnostician or insightful interpreter who cannot “connect” with the patient in this manner will miss valuable information. This issue has been addressed by writers who have pointed out how little understood are the concepts of support and empathy (Peteet 1982).

Being human is also to be a creature of habit and pattern in linguistic, interpersonal, and emotional realms. The skilled psychiatrist listens with this ever in mind. What we see in the interview, what we hear in interactions, may be presumed to be repetitions of many other events. The content may vary, but the form, motive, process, and evolution are generally universal for any given individual. This, too, is part of listening. To know what is fundamentally human, to have a well-synthesized rigorous theory, and to hear the person’s unique but repetitive ways of experiencing are the essence of listening. These skills “find” the patient in all his/her humanity, but then the psychiatrist must find the right communication that allows the patient to feel “found.”

To Be Found: The Psychological Product of Being Heard

Psychiatric patients may be lonely, isolated, demoralized, and desperate, regardless of the specific diagnosis. They have lost themselves and their primary relationships, if they ever had any. Stanley Jackson (1992) makes the point that before anything else can happen, they must be found, and feel found. They can only be found within the context of their own specific histories, cultures, religions, genders, social contexts, and so on. There is nothing more healing than that experience of being found by another. The earliest expression of this need is in infancy and we refer to it as the need for attachment. Referring to middle childhood, Harry Stack Sullivan spoke of the importance of the pal or buddy. Kohut spoke of the lifelong need for self-objects.

Figure 1–2 The therapeutic dyad.
In lay terms, it is often subsumed under the need for love, security, and acceptance. Psychiatric patients have lost or never had this experience. However obnoxious or destructive or desperate their overt behavior, it is the psychiatrist’s job to seek and find the patient. That is the purpose of listening.

If we look back to Clinical Vignette 3, wherein the phrase “little fella” bespoke such deep and important unverbalized meaning, the patient’s reaction to the memory and recognition by the psychiatrist was dramatic. He had always known he was different in some indefinable ways from his family. That difference had been both a source of pride and pain to him at various developmental stages. However, the recognition of the specific source, its meaning, and its constant presence in his life created a whole new sense of himself. He had been found by his psychiatrist, who echoed the discovery, and he had found an entire piece of himself that he had enacted for years, yet which had been disconnected from any integrated sense of himself.

Sometimes objectifying and defining the disease/disorder enables the person to feel found. One of the most challenging patients to hear and experience is the acting out, self-destructive, demanding person with borderline personality disorder. Even as the prior sentence conveys, psychiatrists often experience the diagnosis as who the patient is rather than what she suffers. The following case conveys how one third-year resident was able to hear such a patient, and in his listening to her introduce the idea that the symptoms were not her but her disorder.

**Clinical Vignette 11**

A young man with paranoid schizophrenia had been admitted in 1979 to the hospital following a near lethal attack on his father. When asked about this incident, he became frankly delusional, speaking of the Arab–Israeli conflict, the preciousness of Jerusalem, how the Israelis must defend it at all costs. Unspoken was his conviction that he was like the Israelis, with the entire world attacking and threatening him. He believed his father had threatened and attacked him when, in fact, his father had done little more than seek to be closer, more comforting, and advising with the patient. The psychiatrist understood the patient to be speaking of that core of selfhood that we all possess, which, when threatened, creates a sense of vulnerability and panic, a disintegrating anxiety unlike any other. The psychiatrist spoke to the patient of Anwar Sadat’s visit to Jerusalem and engaged him in a discussion of how that had gone, what the outcome had been, had the threat been lessened or increased. The patient, although still delusional, visibly relaxed and began to speak much more directly about his own sense of vulnerability and uncertainty over his personal integrity and its ability to withstand any closeness. He still required neuroleptic medication for his illness; however, his violent thoughts and behaviors reduced dramatically. He was able to begin interacting with his father, and his behavior on the ward changed as well.

Gender can play a significant role in the experience of feeling found. Some individuals feel that it is easier to connect with a person of the same sex, and others, with someone of the opposite sex. Clinical Vignette 6 is an excellent example of this. In these days of significant change in and sensitivity to sex roles, a misinterpretation such as that early in treatment could result in a permanent rupture in the alliance. Psychiatrists vary in their sensitivity to the different sexes. Some may do better with those who have chosen more traditional roles, and others may be more sensitive to those who have adopted more modern roles.

We now know that just as there is a neurobiological basis for empathy and countertransference, there is a similar biological basis for the power of listening to heal, to lift psychological burdens, to remoralize, and to provide emotional regulation to patients who feel out of control in their rage, despair, terror, or other feelings (Table 1–5). Attachment and social support are psychobiological processes that provide necessary physiological regulation to human beings. This has been shown by the work of Hofer (1996), Cobb (1976), Meaney (2001), Nemeroff (Heim and Nemeroff 2001), and many others. Additional work of Paul Ekman (1992) supports the notion of the patient’s capacity to perceive empathy through the powerful nonverbal, universally understood communication of facial expressions. His research in basic human emotions sets forth the idea of their understanding across cultures and ages. It further supports the provocative idea that facial expressions of the listener may generate autonomic and central nervous system changes not only within the listener but within the one being heard, and vice versa. Indeed, the evidence is growing that new experiences in clinical interactions create learning and new memories, which are associated with changes in both brain structure and function (Kandel 1999, Gabbard 2000, Mohl 1987, Liggan and Kay 1999, Siegel 2006). When we listen in this way, we are intervening not only in a psychological manner to connect, heal, and share burdens but also in a neurobiological fashion to regulate, modulate, and restore functioning. When patients feel found, they are responding to this psychobiological process.

**Listening to Oneself to Listen Better**

To hold in mind what has been said and heard after a session and between sessions is the most powerful and active tool of listening. It is a crucial step often overlooked by students and those new at listening. It is necessary to hear our patients in our thoughts during the in-between times in order to pull together repetitive patterns of thinking, behaving, and feeling, giving us the closest idea of how patients experience themselves and their world. In addition, many of our traumatized patients have not had the experience of being held in mind, of being remembered, and their needs being thought of by significant others. These key experiences of childhood affirm the young person’s psychological being. It is important to distinguish this kind of “relistening” to the patient—an important part of the psychiatrist’s ongoing
processing and reprocessing of what has been heard and experienced—from what some may leap to call countertransference. One way of identifying this distinction would be to differentiate listening to oneself as one reviews in one’s mind the patient’s story versus becoming preoccupied and stuck with one’s thoughts and feelings about a particular aspect of a patient.

Clinical Vignette 12

He was working the midnight Friday to 11 a.m. Saturday shift in a Psychiatric Emergency Room. The patient was a 26-year-old woman brought in by ambulance after overdosing on sertraline following an argument with her boyfriend. She had been partying with him and became enraged at the attention he was paying to the date of a friend who was accompanying them. After being cleared medically, the patient was transferred to psychiatry for crisis intervention. It was about 4 a.m. when she arrived. She was crying and screaming for the psychiatric staff to release her. In the emergency department she had grabbed a suture scissors attached to the uniform of the charge nurse. The report was given to the psychiatric resident that she had been a “management problem” in the medicine ER.

The psychiatrist sat wearily and listened to the patient tell her story with tears, shouts, and expletives sputtered through clenched teeth. She stated that she did not remember ever being happy, that she frequently had thoughts of suicide, and that she had overdosed twice before, following a divorce from her first husband at the age of 19 and then 8 months prior to this episode when she had been fired from a job for arguing with her supervisor. Her parents had kept her 6-year-old and 7-year-old sons since her divorce. She was currently working as a file clerk and living with her boyfriend of 2 months. She stated that she felt like there was a cold ice cube stuck in her chest as she watched her boyfriend flirting with the other woman. She acknowledged that she felt empty and utterly alone even in the crowded bar. She created an unpleasant scene and they continued to argue until they got home. Then he had laughed at her and left, stating that he would come back when she had cooled down.

The resident sat quietly and listened. He looked dreary. The night had been a busy one. She looked at him and complained, “Don’t let me and my problems bore you!” He looked at her and said, “Quite the contrary. I’ve been thinking as you speak that I know what disorder you suffer from.” With that statement, he pulled out the DSM-IV-TR and read with her the description of the symptoms and signs of borderline personality disorder. She had been in therapy off and on since she was 16 years old. No one had ever shared with her the name of the diagnosis but instead had responded to her as if the disorder was the definition of who she was. In his listening, he was able to hear her symptoms as a disorder and not the person. And in his ability to separate the two, he was able to allow her to distance herself from the symptoms, too, and see herself in a new light with her first inkling of her own personhood.

As the verbal interaction with the patient occurs, psychiatrists may find themselves expressing thoughts and feeling in ways that may be quite different from their usual repertoire. The following case is an example.

This sort of listening to oneself in order to understand the patient requires a good working knowledge of projective identification (Ogden 1979). Projective identification, first defined by Melanie Klein, describes a defense mechanism in which the patient, in an effort to master intolerably terrifying emotions, unconsciously seeks to engender them in the therapist and to identify with the psychiatrist’s ability to tolerate and handle the feelings.

Clinical Vignette 13

A second-year resident, rotating through an inpatient unit that serves the psychiatric needs of very severely ill psychotic patients with multiple admissions, dual diagnoses, homelessness, criminal records, significant histories of medical noncompliance, and, in some, unremitting psychosis, was particularly struggling with a 33-year-old white woman admitted for the 11th time since age 19. The patient invariably stopped medications shortly after discharge, never kept follow-up appointments, and ended up on the streets psychotic and high on crack cocaine. She would then be involuntarily committed for restabilization. And so the cycle would repeat itself. The resident would see the patient on daily rounds. The patient’s litany was the same day after day: “I’m not sick. I don’t need to be here. I don’t need medicines.” And regularly she refused doses.

The resident spoke often of her patient to other residents in her class and often found herself ruminating about the patient’s abject loneliness. She began her regular supervision hours either frustrated or feeling hopeless that anything would change with this patient because the patient flatly refused to acknowledge her disorder. The patient’s level of denial was of psychotic proportions. Shortly after a particularly difficult encounter with the patient concerning her refusal to take an evening dose of haloperidol, the resident came to supervision with the report that she had awakened terrorized by dreaming the night before that she had been diagnosed with schizophrenia. She had been intensely affected by overwhelming pain, confusion, and despair as she heard the diagnosis in her dream. “IT CAN’T BE!!!” she screamed, waking herself with a shaking start. “I’m NOT SICK!! I DON’T NEED TO BE HERE!!! I DON’T NEED MEDICINE!!!” The words of her patient echoed in her mind as her own echoed in her ears. She had taken the patient’s story and words home with her and kept them in mind at an unconscious level to be brought up in her dream, the ultimate identification with the patient. How more intensely can one be empathic with her patient than to dream as if she is experiencing the same horrifying reality? The patient and resident continued to struggle, but after the dream the resident was able to approach the patient and her story from a position of understanding the patient’s need to maintain a lack of awareness or absence of insight. To acknowledge the presence of the disorder was more than the patient’s already fragmented ego could bear. And now the resident “heard” it.

Clinical Vignette 14

A 45-year-old divorced white woman, being followed for bipolar disorder and borderline personality traits and stable for several years on lithium, was in weekly psychotherapy. During the prior weekend she had moved into another apartment closer to her work. On the day of the move, she overslept and woke up with a start. The admonition to herself as she awoke was, “You lazy bitch!
You can never manage on your own.” She had earlier, as a child, experienced a mother who was needy, engulfling, punishing, hostile, critical, and dependent upon the patient. Her therapist, having some knowledge of the patient and her background, said, “Your mother is still with you. It was she in your head continuing to bombard you with derogatory statements.” The same patient was often 10 or 15 minutes late for sessions, and her therapist found herself irritated at the patient’s habitual tardiness. To her own surprise and enlightenment, the therapist also found herself thinking, “What a chaotic woman! She’ll never manage to be here on time.” She, too, had heard the voice of her patient’s mother. In the next session she wondered with her patient if she found herself wishing to place her therapist in the position of her mother, wanting at once to be engulfed and punished.

Clinical Vignette 15

A psychiatrist was treating a 40-year-old man who was in the process of recognizing his own primary homosexual orientation. In the course of treatment he became enraged, suicidal, and homicidal. After one session, the psychiatrist, while driving home, experienced the fantasy that when he got home he would find his patient already there, having taken the psychiatrist’s family hostage. The psychiatrist became increasingly terrified, even outright paranoid that this fantasy might actually come to pass. The patient was a computer expert who had indeed discovered the unlisted phone number and address of his therapist. But the psychiatrist realized that this fantasy was far out of keeping with his own usual way of feeling and the patient’s way of behaving and viewing him. On arriving home to discover his family quite safe, the psychiatrist called the patient and scheduled him as his first for appointment the following morning. When the patient arrived, the psychiatrist said, “You know, I think I’m only now beginning to appreciate just how terrified and desperate all of this makes you.” The patient slumped down into his chair, heaved a sigh, and said, “Thank God!”

Listening in Special Clinical Situations

Children

Listening to younger children often involves inviting them to play and then engaging them in describing what is happening in the play action. The psychiatrist pays careful attention to the child’s feelings. These feelings are usually attributed to a doll, puppet, or other humanized toy. So if a child describes a stuffed animal as being scared, the psychiatrist may say, “I wonder if you, too, are scared when…” or “That sounds like you when…” The following case is an example.

Geriatric Patients

Working with the elderly poses its own special challenges. These challenges include not only the unique developmental issues they face but also the difficulty in verbalizing a lifetime of experience and feelings and, commonly, a disparity in age and life experience between the clinician and the patient.

It is challenging to elicit the elements of a story, especially when they span generations. The elderly are often stoic. In the face of losses that mark the closing years of life, denial becomes a healthy tool allowing one to accept declining abilities and the loss of loved ones. The psychiatrist must appreciate that grief and depression can often be similar in some respects.

Clinical Vignette 16

A 4-year-old boy was brought in for psychiatric evaluation. He and his father had come upon a very serious automobile accident. One person had been thrown from the car and was lying clearly visible on the pavement with arms and legs positioned in grotesque angles, gaping head wound, obviously dead. The child’s father was an off duty police officer who stopped to assist in the extraction of two other people trapped in the car. The father kept a careful eye on the youngster who was left in the car. The child observed the scene for about 30 minutes until others arrived on the scene and his dad was able to leave. That night and for days to come, the child preoccupied himself with his toy cars that he repetitiously rammed into each other. He was awakened by nightmares three times in the ensuing weeks. During his evaluation in the play therapy room, he engaged in ramming toy cars together. In addition, he tossed dolls about and arranged their limbs haphazardly. As he was encouraged to put some words to his action, he spoke of being frightened of the dead body and of being afraid to be by himself. He was afraid of the possibility of being hurt himself. He came in for three more play sessions, which went much the same way. His preoccupation with crashing cars at home diminished and disappeared as did the nightmares. The content of his play was used to help him put words and labels on his scar.

Chronically Mentally Ill

Listening to the chronically mentally ill can be especially challenging, too. The unique choice of words characteristic of many who have a thought disorder requires that the physician search for their meanings and those of phrases that may be peculiar and truly eccentric. Clinical Vignettes 1, 10, and 12 are examples of this important challenge for the psychiatric listener.

Clinical Vignette 17

A psychiatrist was asked to examine an 87-year-old white man whom the family believed to be depressed. They stated that he was becoming increasingly detached and disinterested in the goings-on around him. When seen, he was cooperative and compliant, but he stated that he did not believe he needed to be evaluated. The patient had faced multiple losses over the past few years. After retiring at the age of 65, he had developed the habit of meeting male friends at a coffee shop each morning at 7 a.m. Now, all but he and one other were dead, and the other was in a nursing home with the cognitive deficits of primary dementia of the Alzheimer’s type, preventing his friend from recognizing him when visiting. The patient’s wife had died 13 years before after many years of marriage. He had missed her terribly at first but then after a year or so he got on with his life. Several years later, he suffered a retinal detachment that impaired his vision to the point that he was no longer able to drive himself to get about as he once had. What he missed most was the independence of going
Clinical Vignette 17 continued

... care for her. He had been particularly close to her because she had been her caretaker all her life. Although he denied feelings of guilt, he said that it “wasn’t right” that he had outlived the youngest member of his family. His family said that he had taken her death especially hard and was tearful and angry. The focus of his anger during the final stages of her illness was at the young doctors whom he perceived as having given up on her. After her death, it fell to him to dispose of her accumulated possessions as she had no children and her husband had preceded her in death many years before. At first he said that he couldn’t face the task. Finally, some 2 months later, he was able to close her estate. During that period of time, he had significant sleep disturbance, reduced energy, and his family often experienced him as crotchety and complaining. They and the patient attributed it to mourning her loss. However, recently he was emotionally detached, not very interested in life around him, and they found it particularly alarming that he had said to his son that he was “ready to die.” What did all this mean? Was he depressed? Was he physically ill, creating the sense of apathy and disinterest? Was he grieving? He was not suicidal. He did not suffer negative thoughts about his own personhood. He was not having thoughts that he had let anyone down. Together, he and the psychiatrist decided that he was indeed grieving. This time, he was grieving for his own decline and imminent death. He, in fact, was in the final acceptance phase of that process. In a family meeting, in the discussions about the feelings of each member of the family, it became apparent that he was facing the end of life, which evoked many emotions in those who loved him.

Clinical Vignette 19

A 32-year-old black woman who had multiple hospitalizations for schizophrenia and lived with her mother was seen in the community psychiatric center for routine medication follow-up. Her psychiatrist found her to have an increase in the frequency of auditory hallucinations, especially ones of a derogatory nature. The voices were tormenting her with the ideas that she was not good, that she should die, that she was worthless and unloved. Her psychiatrist heard her say that she had wrecked her mother’s car 2 weeks previously. The streets had been wet and the tires worn. She had slid into the rear of a car that had come to an abrupt stop ahead of her on a freeway. Although her mother had not been critical or judgmental, the patient felt overwhelming guilt as she watched her mother struggle to arrange transportation for herself each day to and from work.

Growing and Maturing as a Listener

Transference/countertransference influence not only relationships in traditional psychotherapy but also interactions between all physicians and patients; it is omnipresent as a filter or reverberator of that which is heard. Even the most experienced of listeners are not always aware of the ways in which their patients’ stories are impacted by countertransference. Patients come, too, with tendencies and predispositions to experience the listener, the other person in the therapeutic dyad, in a familiar but distorted fashion. The patient may idealize and adapt to interpretations. She/he may be hostile and distrustful, identifying the psychiatrist unconsciously with one who has been rejecting in the past. Listening to the “flow of consciousness,” the psychiatrist discerns a thread of continuity and purposefulness in the patient’s communications. As the psychiatrist becomes more familiar with his patient, he discovers the connections between threads and the meaning becomes apparent. This awareness may come as a sign and symptom, fantasy, feeling, or fact.

There is an increasing recognition that to be a healing listener one must be able to bear the burden of hearing what is told. Like the patient, we fear what might be said. A patient’s story may be one of rage in response to early childhood attachment ruptures or abuse, of sadness as losses are remembered, or of terror in response to disorganization during psychotic breaks. The patient’s stories invariably evoke anger, shame, guilt, abject helplessness, or sexual feelings within the listener. These feelings, unless attended to, appreciated, and understood will block the listening that is essential for healing to take place. Every insight is colored by what the listener...
The best psychiatrists continue all their professional lives to learn how to listen better. This may be thought of not only as a matter of mastering countertransference but also of self education. One must learn to recognize when there are impasses in the treatment and to seek education, from a colleague or, perhaps, even from the patient. Consider these two examples.

How can the psychiatrist’s demeanor convey to the patient that he is safe to tell his story, that the listener is one who can be trusted to be with him, to worry with him, and serve as a helper? Much is written about the demeanor of the psychiatrist. The air, deportment, manner, or bearing is one of quiet anticipation—to receive that which the patient has come to tell and share in the telling. Signals of anticipation and curiosity may be conveyed by such statements as “I’ve thought about what you said last time,” “How do you feel about . . . ?” “What if . . . ?”

Clinical Vignette 21

A Jewish resident was treating an 8-year-old Catholic boy who came in one day and mentioned offhandedly that he was about to go to his first confession. The psychiatric resident made no particular note of the issue and kept on listening to the boy’s play and its themes. He noted that guilt, which had been an ongoing theme, was prominent again. When he presented the session in supervision the supervisor wondered about the connection. It emerged that there was a large gulf between the therapist and the boy. Jewish concepts of sin and atonement are different from Christian ones, and the rituals surrounding them have rather different intentions and ideas of resolution. The resident had missed the opportunity to explore the young boy’s first introduction, within his religious context, to the belief in a forgiving God, a potentially important step in helping the child to resolve his ongoing struggles with guilt over his own greedy impulses.

Clinical Vignette 22

A psychiatrist began treating a Nigerian native who was suffering from posttraumatic stress disorder after being assaulted at work. After several sessions, the psychiatrist felt a sense of being at a loss in terms of what the patient was expecting out of their work and how the therapist was being seen by the patient. He then took several sessions to inquire of the patient about his tribe, its structure, family roles, definitions of healing, ideas of illness and wellness, etc. After this exploration, the psychiatrist adopted a different stance with the patient, heard the patient’s communications very differently, and the therapy proceeded much more smoothly and comfortably to a successful conclusion.

Efforts of clarification often serve as bridges between sessions and communicate that the listener is committed to a fuller understanding of the patient. Patients have the need to experience the psychiatrist as empathic. Empathy describes the feeling one has in hearing a story that causes one to conjure up or imagine how it would have been to actually have had an experience oneself. How does one integrate all this so that it is automatic but not deadened by automaticity? How does the psychiatrist continue to hear the “same old thing” with freshness and renewal? How does one encourage the patient with consistency, clarity, and assurance in the face of uncertainty and occasional confusion? Not by assurance that everything will be all right when things might probably not be. Not by attempting to talk the patient into seeing things the clinician’s way but rather by the psychiatrist’s having the capacity to hear things his patient’s way, from the patient’s perspective.

Psychiatry is one of those rare disciplines where the experience of listening over and over again allows the listener...
to grow in their capacities to hear and to heal. Hopefully, we get better and better as the years advance, become smoother, and develop a style that blends with our personality and training. We are renewed by the shared experiences with our patients.

Clinical Vignette 23

A Psychiatrist with 22 years of experience had recognized during his residency and early career that although he could effectively care for schizophrenic patients in a variety of settings, but when he attempted to follow them as outpatients, invariably they dropped out of treatment. The psychiatrist assumed that this must reflect some block he had based on having been partly raised by a relative with schizophrenia. Though the psychiatrist had engaged in his own therapy and done much soul-searching on the subject, the clinical limitation continued and the clinician simply accepted that this would be a group of patients he would have to refer for ongoing outpatient care.

However, after many years of experience, the psychiatrist decided to try once more. He began following a young man with paranoid schizophrenia who was on a complicated psychopharmacologic regimen. The course was stormy with periodic hospitalizations, but reasonably successful for several years until the patient began to have suicidal ideation and to call the psychiatrist after hours, something that had not been part of the clinical picture. The clinician found himself becoming very agitated and angry to the point where he realized his judgment might be distorted. He arranged hospitalization one weekend evening and resolved to work with the hospitalist then next day to transfer the patient to someone better equipped to meet his needs. That night, the psychiatrist had a dream. All he could recall was that his relative with schizophrenia was in it, and he awoke with the most profound feeling of helplessness he had ever experienced.

With the careerlong block now clarified, the psychiatrist approached the patient very differently and has continued to treat him successfully for 5 further years, comfortable at long last with his role as sharing the burden of this extraordinary illness with the patient.

To hear stories of the human condition reminds the psychiatrist that he, too, is human. There is time to make discoveries in the patient’s stories from previous times, and maybe in previous patients. Patients will always endeavor to tell their stories. The psychiatrist continues to grow by being the perpetual student, always with the ear for the lesson, the remarkable life stories of his patients.

Chapter 1 • Listening to the Patient

For centuries, healers had little understanding of disease and lacked the technologies we now know are necessary for the treatment and cure of many diseases. Physicians had few medications, and surgery was only a last resort. In fact, the most important tool for healing was the relationship between the physician and the patient. Interpersonal relationships have a powerful influence on both morbidity and mortality (House et al. 1988). Social connectedness enhances health in both direct and indirect ways: directly regulating many biological functions, decreasing anxiety, providing opportunities for new information, and fostering alternative behaviors (Hofer 1984). We know little about the basic mechanisms by which interpersonal relationships, and the physician–patient relationship in particular, operate (Ursano and Fullerton 1991). However, clinical wisdom holds that both the reality-based elements of the physician–patient relationship—in modern times referred to as the working alliance or the therapeutic alliance (Greenson 1965, Zetzel 1956)—and the fantasy-based elements of that relationship affect the patient’s pain, suffering, and recovery from illness.

Physicians learned through trial and error to interact with their patients in ways that relieved pain and promoted health (Frank 1971). Often the physician’s only interventions were reassuring patients, providing knowledge about the patient’s disease, and accepting the patient’s feelings of distress as normal. In this way, physicians increased patient’s expectations of improvement and maximized their hope for the future. Although these interventions, based on wisdom and intuition, are no longer the only tools available to the physician, they continue to be an important part of the physician’s and particularly the psychiatrist’s therapeutic armamentarium.

The physician–patient relationship is also a source of information for the physician. The way the patient relates to the physician can help the physician understand the problems the patient is experiencing in her or his interpersonal relationships. The nature of the physician–patient relationship can also provide information about relationships in the patient’s childhood family, in which interpersonal patterns are first learned. With this information, the physician can better understand the patient’s experience, promote cooperation between the patient and those who care for her or him, and teach the patient new behavioral strategies in an empathic manner, understanding the patient’s subjective perspective, that is, the patient’s feelings, thoughts, and behaviors.

**The Placebo Effect**

The nonspecific aspects of cure are often thought to be mystical or mysterious. In fact, in biological studies they are recognized as the placebo effect. Oddly, these effects of interpersonal relationships are both one of the prized and one of the most denigrated aspects of all of medicine. Yet, as clinicians, we all strive to alleviate our patients’ pain and suffering and return them to health as soon as possible with whatever tools may help. Many well-designed studies show that 20–30% of subjects respond to the placebo condition. Recent studies show that analgesic placebo has similar neural mechanisms to opioid analgesia (Petrovic et al. 2002). The expectation of symptom improvement has been thought to play a critical role in the placebo effect and has been associated with increased endogenous striatal dopamine release in Parkinson’s disease and increased endogenous opioid transmission in placebo analgesia. Neuroimaging studies such as functional magnetic imaging and positron emission tomography suggests that expectations of improvement are associated with the frontal cortical areas, especially the dorsolateral prefrontal, orbitofrontal and anterior cingulated cortices, as well as with the ventral striatum (Lidstone and Stoessl 2007). The problem with placebos is not whether they work but that we do not understand fully how they work and, therefore, we do not have control over their effects. As a physician, one strives to maximize one’s interpersonal healing effects and, in this way as well as with other healing tools, increase the chances of our patients’ relief from pain and of recovery.
Roles and Motivations
The physician–patient relationship includes specific roles and motivations. These form the core ingredients of the healing process. In its most generic form the physician–patient relationship is defined by the coming together of an expert and a help seeker to identify, understand, and solve the problems of the help seeker. The help seeker (in modern terms, the patient) is motivated by the desire and hope for assistance and relief from pain (Sullivan 1954). A physician is required to have a genuine interest in people and a desire to help (Lidz 1983). Simply stated, “the secret of the care of the patient is in caring for the patient” (Peabody 1927). Caring about and paying attention to a patient’s suffering can yield remarkable therapeutic dividends. More than one attending physician has been reminded of this when a patient deferred making a treatment decision until he or she was able to consult with “my doctor,” who turned out to be the medical student. Interestingly, the doctor–patient relationship has evolved over the ages from a paternalistic model of interaction to one that is more balanced, collaborative, and patient centered (Kaba and Sooriamaran 2007). This approach has been described as one where “the physician tries to enter the patient’s world, to see the illness through the patient’s eyes” (McWhinney 1989).

The relationship between the physician and the patient is essential to the healing of many patients, perhaps particularly so for many psychiatric patients. The physician who can skillfully recognize the patient’s half-hidden comment that he or she has not been taking the prescribed medication, perhaps hidden because of feelings of shame, anger, or denial, is better able to ensure long-term compliance with medication as well as to motivate the patient to stay in treatment. Regardless of the type of treatment—medication management, biofeedback, hospitalization, or psychotherapy—the relationship with the physician is critical to therapeutic outcome.

Modern Medicine and the Physician–Patient Relationship
Modern medicine emphasizes a specific role for the physician in the relationship with the patient. In many Western countries, the patient comes for help with a specific problem, the doctor’s office staff secures permission from a third-party payer for the doctor to conduct a particular treatment, a prescribed intervention, which will take a specified amount of time. Decades ago, when the doctor was neighbor, advisor, and friend to the patient and was routinely invited to important family events in the patient’s life such as weddings of children, and when doctors routinely cared for more than one generation of the same family, the physician typically assumed that he or she would be a source of strength and assistance to the patient throughout the cycle of life. This meant more than curing a specific disease or relieving a specific pain.

Although today’s patients may not consciously expect that the physician’s influence and healing powers will take many forms in a complex interpersonal relationship, human nature is still the same, and patients still want from their doctors many nonspecific forms of emotional support which can promote a sense of well-being and better health. Though modern doctors may feel a great deal of time pressure to see many patients each day and to narrowly focus their healing efforts, the physician must also be sensitive to the many needs of patients, who believe that the physician is possessed of wisdom and understanding. Sensitivity to such desires and needs will promote effective and ultimately efficient medical care in all specialties, with all patients. A view that such patients are unusually needy and demanding will not serve the cause of effective medical care.

In today’s technology-driven medicine, the importance and complexity of the physician–patient interaction are often overlooked. The amount of information the medical student or resident must learn frequently takes precedence over learning the fine points of helping the patient relax sufficiently to provide a thorough history or to allow the physician to palpate a painful abdomen. Talking with patients and understanding the intricacies of the physician–patient relationship may be given little formal attention in the medical school curriculum. Even so, medical students, residents, and staff physicians recognize, often with awe, the skill of the senior physician who uncovers the lost piece of history, motivates the patient who had given up hope, or is able to talk to the distressed family without increasing their sense of hopelessness or fear. Systematic review of randomized clinical trials and analytic studies of physician patient communication have demonstrated a positive influence of quality communication on health outcomes (Teutsch 2003). Frequent use of computers, telemedicine, and email as regular means of communicating with and relating to patients complicates the physician–patient relationship even further. Issues of confidentiality, trust, boundaries, and expectations of physician availability can affect the quality of the working relationship (Pearce and Trumble 2006, Spielberg 1998).

Finally, in today’s mobile and geographically evermore united world, the importance of recognizing the needs of patients from parts of the world other than that of the physician’s is a challenge to the practitioner. The physician must be open to the limitations of his or her knowledge of the expectations, beliefs, and likely behavior of patients from different cultures, nations, religions, and ethnic and socioeconomic backgrounds. The physician must recognize this challenge and, one hopes, embrace it with enthusiasm. It can make the practice of medicine a more exciting experience.

Clinical Vignette 1

A 20-year-old female patient suffered a painful athletic injury. She was unsure exactly how her injury had occurred, but she did recall falling on her shoulder on the tennis court while running after a sharply hit ball. She went to the physician fearing that she had damaged her collarbone. When she was informed that there was no fracture, that her pain was due to a bruised muscle and would go away with ice, heat, and aspirin, she immediately felt better. Not only was she relieved but also her perception and experience of the pain actually changed: “It doesn’t seem to hurt as much now.”

Clinical vignettes described throughout this chapter illustrate that the physician–patient relationship is composed of both the reality-based component (the working alliance or therapeutic alliance) and the fantasy-based component (the transference) derived from the patient’s patterns of interpersonal behavior learned in childhood. Either or both of these may maximize or limit the patient’s sense of reassurance, available information, feelings of comfort, and sense of hope (Meissner 1996). In this way, the nonspecific
Attachment Theory and the Physician–Patient Relationship

Attachment theory has been thought to play a significant role in the physician–patient relationship. It postulates that the innate need to form strong attachments to early caregivers is a basic component of human nature and is important in the formation and maintenance of relationships, in developing a sense of security and ultimately in survival (Thompson and Ciechanowski 2003). On the basis of the early experience of the responsiveness and accessibility of caregivers, a person develops expectations of the likely behavior of others and also one’s own style of relating to people throughout one’s life (d’Elia 2001). A doctor responsive to a patient’s verbal and nonverbal needs may be seen as a supplementary attachment figure. Attachment theory has been widely applied to the physician–patient relationship in those with chronic medical illness and also in the palliative care setting (Tan et al. 2005).

Insecure attachment styles (dismissing, preoccupied, and fearful) have been shown to affect the physician–patient relationship and medical treatment outcomes. Ciechanowski et al. 2001 evaluated 367 patients with type 1 and type 2 diabetes in a health maintenance organization’s primary-care setting. Those with dismissing attachment styles tend to undervalue the need for relationships, to minimize symptoms and to be overly self-reliant. They found that these patients had significantly worse glucose control than those with a preoccupied or secure attachment. The patients with dismissing attachment style were also more likely to have poorer glucose control and higher glycosylated hemoglobin levels. They were less likely to take oral hypoglycemics and monitor their blood glucose. Overall, the quality of their doctor–patient relationships was poorer and within this group those that rated the quality of the communication with their provider as poor had higher glycosylated hemoglobin levels compared to those who rated the communication as good.

An additional study by Ciechanowski et al. (2004) examined the influence of patient attachment style on self-care and outcomes through a population-based mail survey. They collected data on 4095 patients with diabetes from nine different primary-care clinics and found that dismissing attachment styles were associated with significantly lower levels of exercise, foot care, and higher rates of smoking and that these associations were mediated through the doctor–patient relationship.

Formation of the Physician–Patient Relationship

Assessment and Evaluation

The physician–patient relationship develops during the assessment and evaluation of the patient. The patient observes the thoroughness and sensitivity with which the physician collects information, performs the physical examination, and explains needed tests. At each step, the physician’s clarification of the treatment goals and interventions either builds up the patient’s expectation of help and feelings of safety or creates increasing distress and disease for the patient. In many aspects and, in particular, in the physician’s compassion and patience, he/she is like a good teacher, establishing the context in which learning and growth may occur and anxiety decrease (Banner and Cannon 1997). Alertness to the patient’s fears and misunderstandings of the evaluation process can minimize unnecessary disruptions of the relationship and provide information on the patient’s previous experiences with medical care and important authority figures. These past experiences form the patient’s present expectations of either help or disappointment (Smith and Thompson 1993) (Table 2–1).

Rapport

Early in the relationship between a psychiatrist and a patient, the patient requests help with his or her pain, uncertainty, or discomfort. The psychiatrist initiates the "contract" of the relationship by acknowledging the patient's pain and offering help. In this action, the psychiatrist has recognized the patient's ill health and acknowledged the need for and possibility of removing the disease or illness. In this first stage of the development of rapport, the way of relating between the physician and the patient, the physician–patient relationship has begun to organize the interactions. Through the physician's and the patient's shared recognition of the patient's pain, the basis for rapport—a comfortable pattern of working together—is established.

The psychiatrist's ability to empathize, to understand in feeling terms every patient's subjective experience, is important to the development of rapport. Empathy is particularly important in complex interpersonal behavioral problems in which the environment (family, friends, schools, caretakers) may wish to expel the patient, and the patient has therefore lost hope. Suicidal patients, adolescents involved in intense family conflicts, and patients in conflict with their medical caregivers can often be convinced to cooperate with the evaluation only when the psychiatrist has shown accurate empathy early in the first meeting with the patient. When the physician acknowledges the patient's pain, the patient feels less alone and inevitably more hopeful (Marziali and Alexander 1991). This rapport establishes a set of principles and expectations for the physician–patient interaction. On this basic building block, more elaborate goals and responsibilities of the patient can be developed.

Clinical Vignette 4

A young man sought treatment for ill-defined reasons: he was dissatisfied with his work, his social life, and his relationship with his parents. He was unable to say how he thought the psychiatrist could help him, but he knew he was experiencing emotional pain: he felt sadness, anxiety, inhibition, and loss of a lust for living. He wanted help.

The psychiatrist noted the patient's tentative style and heard him describe his ambivalence toward his controlling and directing father. With this in mind, the psychiatrist articulated the patient's wish for help and recognized with him his confusion about what was troubling him. She suggested that through discussion they might define together what he was looking for and how she might help him. This description of the evaluation process as a joint process of discovery established a rapport based on shared work that removed the patient's fears of control and allowed him to feel heard, supported, and involved in the process of regaining his health.

The Therapeutic or Working Alliance

For a patient to trust and work closely with a physician, it is essential that there be a reality-based relationship outside the conflicted ones for which the patient is seeking help (Friedman 1969, Rawn 1991). With more disturbed patients, considerable skill is required of the physician to reach this reality-based part of the patient and decrease the patient's fears and expectations of attack or humiliation. Even for healthy patients, the physician must bridge the gap between the patient and the physician that is always present because of their different backgrounds and perceptions of the world. This gap is an expectable result of differences between the physician's and the patient's culture, gender, ethnic background, socioeconomic class, religion, age, or role in the physician–patient relationship. The experienced physician makes communication across the gap seem effortless, using a different "language" for each patient. The student often sees this as an art rather than as a skill to be learned.

The therapeutic alliance is extremely important in times of crisis such as suicidality, hospitalization, and aggressive behavior. But it is also the basis of agreement about appointments, fees, and treatment requirements. In psychiatric patients, this core component of the physician–patient relationship can be disturbed and requires careful tending. Frequently, the psychiatrist may feel that he or she is "threading a needle" to reach and maintain the therapeutic alliance while not activating the more disturbed elements of the patient's patterns of interpersonal relating.

The therapeutic or working alliance must endure in spite of what may, at times, be intense, irrational, delusional, characterologic, or transference-based feelings of love and hate. The working alliance must outweigh or counterbalance the distorted components of the relationship. It must provide a stable base for the patient and the physician when the patient's feelings or behaviors may impair reflection and cooperation. The working alliance embodies the mutual responsibilities both physician and patient have accepted to restore the patient's health. Likewise, the working alliance must be strong enough to ensure that the treatment goes forward even when both members of the dyad may doubt that it can. The alliance requires a basic trust by the patient that the physician is working in his or her best interests, despite how the patient may feel at a given moment. Patients must be taught to be partners in the healing process and to recognize that the physician is a committed partner in that process as well. The development of common goals fosters the physician and patient seeing themselves as having reciprocal responsibilities: the physician to work in a physician-like fashion to promote healing; the patient to participate actively in formulating and supporting the treatment plan, "trying on" more adaptive behaviors in the chosen mode of treatment, and taking responsibility for his or her actions to the extent possible (Ursano and Silberman 1988). The relationship must be able to tolerate periodic review of progress toward these goals—both successes and failures.

Important to the reality-based relationship with the patient is the physician's ability to recognize and acknowledge the limitations of her or his knowledge and to work collaboratively with other physicians. When this happens, patients are most often appreciative, not critical, and experience a strengthening of the alliance because of the physician's commitment to finding an answer. When a patient loses
confidence in the physician, it is often because of unacknowledged shortcomings in the physician’s skills. The patient may lose motivation to maintain the alliance and seek help elsewhere. Alternatively, the patient may seek no help.

**Transference and Countertransference**

Transference is the tendency we all have to see someone in the present as being like an important figure from our past (Freud 1958). This process occurs outside our conscious awareness; it is probably a basic means used by the brain to make sense of current experience by seeing the past in the present and limiting the input of new information. Transference is more common in settings that provoke anxiety and provide few cues to how to behave—conditions typical of a hospital. Transference influences the patient’s behavior and can distort the physician–patient relationship, for good or ill (Adler 1980).

Although transference is a distortion of the present reality, it is usually built around a kernel of reality that can make it difficult for the inexperienced clinician to recognize rather than react to the transference. The transference can be the elaboration of an accurate observation into the “total” explanation or the major evidence of some expected harm or loss. Often the physician may recognize transference by the pressure she or he feels to respond in a particular manner to the patient; for example, always to stay longer or not abruptly leave the patient (Sandler et al. 1973).

Transference is ubiquitous. It is a part of day-to-day experience, although its operation is outside conscious awareness. Recognizing transference in the physician–patient relationship can aid the physician in understanding the patient’s deeply held expectations of help, shame, injury, or abandonment that derive from childhood experiences.

Transference reactions, of course, are not confined to the patient; the physician also superimposes the past on the present. This is called countertransference, the physician’s transference to the patient (Table 2–2). Reich observed that the psychotherapist “must be aware of what the material does to him, before he does something with the material” (Reich 1977). The emotional responses evoked by a patient may provide the physician with some sense of who the patient is, how he relates to others, what his internal world is like and what a relationship with this patient may involve (Ivey 2006). Countertransference usually takes one of two forms: concordant countertransference, in which one empathizes with the patient’s position; or complementary countertransference, in which one empathizes with an important figure from the patient’s past (Racker 1968). For example, concordant countertransference would be evident if a patient were describing an argument with his or her boss, and the psychiatrist, perhaps after a disagreement with the psychiatrist’s own supervisor and without having collected detailed information from the patient, felt, “Oh yeah, what a terrible boss.” Similarly, complementary countertransference would be evident if the same psychiatrist felt, “This person (the patient) does not work very hard, no wonder the boss is dissatisfied,” and felt angry with the patient as well. Paying close attention to our personal reactions while refraining from immediate action can inform us in an experiential manner about subtle aspects of the patient’s behavior that we may overlook or not appreciate. In the preceding example, the psychiatrist with the concordant countertransference might be identifying with the patient’s subtle need to fight with authority. The psychiatrist with the complementary countertransference might have identified with the patient’s boss, seeing only the patient’s more passive wishes.

Countertransference occurs in all “sizes and shapes,” more or less mixed with the physician’s past but often greatly influencing the physician–patient relationship. The wish to save or rescue a patient is commonly experienced and indicates a need to look for countertransference responses. When a patient is seriously ill, such as with cancer, we may increasingly want to treat the patient more aggressively, with procedures that may hold little hope, create substantial pain, and perhaps even be against the patient’s wishes. The physician’s feelings of loss of a valued person (in the present and as a reminder of the past) or feelings of failure (loss of the physician’s own power and ability) can often fuel such reactions. More subtle factors, such as the effects of being overworked, can result in unacknowledged feelings of deprivation leading to unspoken wishes for a patient to quit treatment. When these feelings appear in subtle countertransference reactions, such as being late to appointments, becoming tired in an hour, or being unable to recall previous material, they can have powerful effects on the patient’s wish to continue treatment.

Major developmental events in physicians’ lives can also influence their perceptions of their patients. When a psychiatrist is expecting the birth of a child, she or he may be overly sensitive to or ignore the concerns of a patient worried about a significant illness in the patient’s child. Similarly, a physician with a dying parent or spouse may be unable to empathize with a patient’s concerns about loss of a job, feeling that it is trivial.

---

**Clinical Vignette 5**

A psychiatrist was called to evaluate an agitated older adult resident of a nursing home. After she had interviewed the energetic, sad, and anxious patient, the psychiatrist found herself unexpectedly sad, confused, and unsure about what to do. This was not a new case for the psychiatrist, who had treated many similar cases. In considering her response, her thoughts turned to her grandmother with whom she had lived when she was 8 years old, and who had been displaced from her residence and moved to a nursing home in another city by well-meaning children who wanted her near them. After the move, her grandmother had become depressed and disoriented and died 3 months later. The psychiatrist recalled feeling confused at the time of her grandmother’s death, wondering why she had died when she had just moved to an attractive new home. Recalling her confusion, the psychiatrist could think more clearly about her present

patient and wondered if the patient might be depressed. She talked further with the nurses and found symptoms of depression in addition to the nighttime agitation. This new information altered her decision on the type of medication to begin with and the need for psychotherapy in addition to medication.

Defense Mechanisms
All people, including patients, employ mechanisms of defense to protect themselves from the painful awareness of feelings and memories that can provoke overwhelming anxiety. Defense mechanisms are specific cognitive processes: ways of thinking that the mind employs to avoid painful feelings (Freud 1966). They are often characteristic of a person and form a style of cognition (Shapiro 1965). Common defense mechanisms include projection, repression, displacement, intellectualization, humor, suppression, and altruism (Table 2–3).

Defense mechanisms may be more or less mature depending on the degree of distortion of reality and interpersonal disruption they lead to. This patterning of feelings, thoughts, and behaviors by defense mechanisms is involuntary and arises in response to perceptions of psychic danger (Vaillant 1992). The patient’s characteristic defense mechanisms, the cognitive processes used to lower anxiety and unpleasant feelings, can greatly affect the physician–patient relationship. Defense mechanisms operate all the time; however, in times of high anxiety, such as in a hospital or during a life crisis, patients may become much less flexible in the defenses they use and may revert to using less mature defenses.

Clinical Vignettes 6 and 7 are examples of defense mechanisms (conversion and avoidance or repression) affecting the treatment relationship. In Vignette 6, the conversion reaction that resulted in the paralysis expressed both the patient’s anger and his conflict over what to do. In Vignette 7, the physician knew that the forgetting was neither intentional nor conscious but was directed at denying the need for treatment. In these cases, recognizing the defenses was important to knowing how to relate to the patient (Clinical Vignette 6) and avoid a countertransference reaction of anger at the patient for lack of compliance (Clinical Vignette 7).
Mental Status of the Patient

The patient’s mental status is a major determinant of the formation and nature of the relationship with the physician. A young, healthy patient with an acute disorder has different needs and expectations than a somewhat older person who comes for help with a condition that has been present for a number of years. Both differ from the older adult who comes to the physician expecting that the future will be filled with physical and emotional losses.

It can be seen when comparing these two clinical vignettes (8 and 9) that the mental status of the patient helps define the nature of the physician–patient relationship, though in both cases the treatment relationship was of relatively brief duration and ended successfully.

Clinical Vignette 8

A 25-year-old recent law school graduate came to a psychiatrist following a romantic disappointment. He reported that he was very sad because his girlfriend had chosen to move to a different city, which he believed foretold the end of their relationship. He added that he had been having trouble sleeping for several weeks, and was worried because his exhaustion was causing problems in his ability to perform his work. When the physician took a careful history, he learned that this young man had led a successful life, and that his social and sexual development had been quite unremarkable. He had good friends and close friendships, and several girlfriends in his life. He said he would miss his girlfriend, but that he never intended to marry her. The doctor indicated to her patient that sometimes, after such a disappointment, it was quite common for there to be a period of anxiety and that his sadness was a good sign, showing that he had a good capacity to attach and mourn the loss of a close friend. The psychiatrist also suggested that the patient may be more angry with the girlfriend than he had recognized, with which the patient agreed. The doctor prescribed a mild sleep medication, suggesting it may not even be required, and scheduled a follow-up appointment in a month. When the patient returned, he reported that he had used only two of the sleeping pills and had thrown the rest away. He did not want to schedule another appointment; he expressed gratitude to the psychiatrist and they parted company.

Clinical Vignette 9

A 70-year-old widowed lawyer was vigorous, active, financially comfortable, with many friends and professional associates. She explained to the psychiatrist that the last year had, however, been very difficult for her. Six months before, her husband of 45 years had died after a 2-year struggle with congestive heart failure. She now found herself seriously depressed, despite her active life. She was thinking actively about giving up her law practice, which she had previously found interesting and which held the promise of significant financial reward. She went on to say that she had no appetite. She was chronically sleep deprived and was losing interest in her friends, children, and grandchildren. When taking a careful history, the psychiatrist also learned that this patient had suffered from a serious depression 35 years earlier, when she lost a pregnancy, and that this depression lasted for a year. It eventually resolved after she took a tricyclic antidepressant and engaged in brief, insight-oriented psychotherapy. In that therapy, her relationship with her own depressed mother had been discussed. With all this information, the psychiatrist suggested she and her patient meet weekly and that the treatment include a pharmacological intervention to help with the patient’s current depression. This treatment ended successfully 1 year later.

The patient’s mental status in this case (Clinical Vignette 10) was the focus of and major factor in the structure of a long psychotherapy that greatly assisted the rehabilitation of interpersonal skills and the understanding of his cognitive limitations and newly changed cognition. The ability to work with an empathic listener while confronting limitations and feelings of shame and embarrassment is a special opportunity of the well-formed doctor–patient relationship.

Clinical Vignette 10

A 40-year-old man came to a psychiatrist with a long history of emotional difficulties. He had been a healthy and happy college student when he developed a skin abscess, which caused a septicemia and a brain infection. After this, his entire life changed. Although college was quite challenging, he was able to finish it, but had difficulty concentrating, his judgment was poor, his impulse control impaired. He had difficulty remembering words, and he realized that his previously adequate social skills had been lost. Where once he had been charming and known for his sense of humor, now he was dull and in many ways boring. Yet there was more to him than that, and he longed for an opportunity to speak with an understanding listener in the hope that through such a relationship he might be able to make constructive changes in his life. He knew what had been lost, he wanted to understand his limitations better, and he wanted to be able to function well enough to keep a job. A more remote goal was to have a long-term relationship with a woman. His consulting psychiatrist knew that she was to take on this patient it would be for the long haul. Fortunately, there were no financial barriers to treatment, and the pair worked together on a weekly basis for many years. In the course of that treatment, the patient came to understand the social situations that made him anxious and the way his emotional states of mind influenced changes in his cognitive function. He developed the ability to work and love more effectively; he met a woman who was kind and loving. The psychiatrist was invited to his wedding. She attended the religious service but quietly left the reception after congratulating her patient and his wife. By that time, years into the physician–patient relationship, the patient saw his physician as a wise observer, an advisor, and a trusted friend. To the physician, her patient was a happy reminder of how much a person can strive to improve his life, and a rich source of learning about the interaction of emotion, cognitive function, and behavior.

Research on the Physician–Patient Relationship

Research examining the physician–patient relationship has focused primarily on studies of psychotherapy. In general,
The research confirms what clinicians have long recognized: the physician-patient relationship is central to behavioral change in nearly all treatment modalities (Martin et al. 2000). The therapeutic alliance has been and continues to be the most studied aspect of the psychotherapy process (Orlinsky et al. 1994). A relatively large body of research has consistently documented that the quality of the therapeutic alliance correlates positively with therapeutic change across a variety of treatment modalities and clinical issues (Castonguay et al. 2006). Pioneered by Roger’s (1957) view of the therapeutic relationship as providing “necessary and sufficient conditions” of change, psychotherapy process outcome studies have focused both on identifying the effects of particular components of the therapeutic alliance and on identifying the effects of the alliance on outcome (Orlinsky et al. 1994). The literature seems to also indicate that alliance quality correlates positively with some patient characteristics (psychological mindedness, expectation for change, quality of relationships) and negatively with others (e.g., avoidance, interpersonal difficulties, depressogenic cognitions) (Constantino et al. 2002). Research also suggests that certain qualities of the therapist are positively associated with quality alliances (warmth, flexibility, accurate interpretation) while other characteristics may be associated with difficulties with the alliance (rigidity, criticalness, inappropriate self-disclosure) (Ackerman and Hilsenroth 2003). Current research focuses on the patient’s affective relationship to the therapist, the patient’s capacity to work purposefully in therapy, the therapist’s empathic ability, and their mutual agreement on the goals and tasks of therapy (Gaston 1990, Horvath and Luborsky 1993). Psychotherapy outcome research has used meta-analysis to attain efficient and maximally objective integrative summaries of existing studies (Strube and Hartman 1983). Early studies focused on determining the extent of the benefit associated with psychotherapy in the existing literature as a whole, compared the outcomes of different treatments, and examined the impact of methodological features of studies on the reported effectiveness of treatments. Smith and colleagues (1980) found an average effect size of 0.85 standard deviation units for 475 studies comparing treated and untreated groups. This means that, after treatment, the average treated person was better off than 85% of the untreated sample.

Subsequent meta-analytic reviews of specific disorders likewise have yielded promising results. For depression, five meta-analytic reviews totaling 133 studies showed effect sizes ranging from 0.65 to 2.15 standard deviation units. For agoraphobia, three meta-analytic reviews totaling 95 studies showed effect sizes ranging from 1.2 to 2.10 units. For obsessive-compulsive disorder, two meta-analytic reviews totaling 43 studies showed effect sizes ranging from 1.34 to 1.37 units (Lambert and Bergin 1994).

Orlinsky and colleagues 1994 used meta-analysis for more than 2,300 findings on process outcome from approximately 300 psychotherapy studies conducted between 1950 and 1992. They concluded that the strongest evidence supports the importance of the therapeutic alliance to outcome, with more than 1,000 significant findings. The relationship of outcome to therapeutic alliance is particularly strong when the alliance is measured from the patient’s perspective; for example, it is perhaps more important that the patient feels understood and valued than that the therapist thinks this is so. What therapists do, when they do it, and whether they are genuine in doing it all matter to patients, as does the level of the patient’s emotional involvement in the process (Orlinsky et al. 1994). From the perspective of the therapeutic alliance, the therapist contributes to helping the patient achieve a favorable outcome mainly through empathic, affirmative, collaborative, and self-congruent engagement with the patient (Lambert and Bergin 1994).

Although there are many therapies, each with its own theoretical basis and specific techniques, there is only modest evidence to suggest the superiority of one school or technique over another. Common factors, which include the therapeutic alliance, loom large as the major mediators of treatment outcome. Research on specific techniques and research on common factors, however, are not necessarily in opposition (Docherty 1985). A growing number of researchers and clinicians assert that research cannot hope to separate the unique contributions of techniques and common factors to outcome. In this view, techniques are interpersonal and gain their meaning from the particular interaction of the individuals involved (Butler and Strupp 1986, Karasu 1986, Norcross and Goldfried 1992). Studies are needed to investigate the change processes associated with each of the various psychotherapeutic approaches, so as to determine which are common to all and which are unique (Goldfried 1991). Joyce et al. examined meta-analytic reviews of the effectiveness of psychotherapy, the movement to identify empirically supported treatments and research on the “common factor” or “contextual” models of psychotherapy. The studies supported two conclusions: (1) psychotherapy is superior to the absence of treatment and (2) different approaches to psychotherapy showed equivalent results. “Considerable evidence supports the importance of common factors as mechanisms of change; at present however, this relationship is predominantly correlational” (Joyce et al. 2006). Further research is needed to clarify these relationships. A converging of psychotherapeutic techniques from various perspectives will require a new understanding of our psychotherapeutic interventions as well as a rethinking of our methods of teaching, practicing and researching these.

Based on the existing evidence, the therapeutic alliance accounts for much, if not most, of the gains that result from therapy. This confirms the importance of the alliance for change. Further study is needed of the therapeutic alliance in treatment settings other than psychotherapy. In the interim, the data support the notion that physicians may enhance clinical outcomes by intentionally incorporating the components of the therapeutic alliance into their relationships with patients (Lambert and Bergin 1994). Researchers have long debated the meaning of the term alliance in psychotherapy research and many note the limitations of the research secondary to a lack of a “consensual definition of the construct” (Hovarth 2006). Some maintain that the concept of alliance is limited to the more psychodynamically informed psychotherapies. However, others assert that the therapeutic alliance is a universal concept that exists in all treatments regardless of the extent to which it is explicitly formulated theoretically (Meissner 2006). Meissner even conceptualizes the alliance in broader terms than are typically used in research including elements of the therapist’s empathy and neutrality. Others such as
Safran and Muran (2006) propose the alliance should comprise shifts in the quality of the therapeutic relationship at the conscious and unconscious level. It is clear that “greater specificity in identifying the alliance, as part of larger, common therapeutic relationship and within particular theoretical orientations, respectively is an essential step in future work” (Samstag 2006).

Other future directions of research may include a more careful study of the therapeutic processes in which the alliance does not develop or in which it ruptures. In this way, we may better understand the way in which alliance affects outcome (Castonguay et al. 2006). Crits-Christoph et al. (2006) write of the importance of examining for reverse causation, which is the concept that the alliance does not cause the outcome but instead early improvement in therapy creates a positive alliance. Additionally, research needs to examine the possibility of third variables such as patient personality style that might influence both alliance and treatment outcome (Crits-Christoph et al. 2006).

Special Issues in the Physician–Patient Relationship

Phase of Treatment

The treatment phase—early, middle, or late (Table 2–4)—affects the structure of the physician–patient relationship in terms of both the issues to be addressed and the task to be accomplished by the physician and the patient. The early stage of treatment involves developing a rapport, forming shared initial goals, and initiating the working alliance. Education of the patient is important to the success of the physician–patient relationship in this stage, so that the patient learns what he or she can expect. In the middle stage of treatment, the physician and patient continuously refine their shared goals, and various interventions are tried. While this takes place, transference and countertransference are likely to emerge. How these are recognized and managed is critical to whether the relationship continues and is therapeutic.

<table>
<thead>
<tr>
<th>Table 2–4</th>
<th>Key Features of Treatment Phases</th>
</tr>
</thead>
<tbody>
<tr>

<td></td>
</tr>
<tr>
<td>Middle: refining shared goal, using a variety of trial interventions</td>
<td></td>
</tr>
<tr>
<td>Late: assessing outcome, resolving presenting problems, planning for future</td>
<td></td>
</tr>
</tbody>
</table>

In the later phase of treatment, the assessment of the outcome and plans for the future are the primary focus. The physician and the patient discuss the end of their relationship in a process known as termination. Successes and disappointments associated with the treatment are reviewed. The physician must be willing to acknowledge the patient’s disappointments, as well as recognize her or his own disappointments in the treatment. The therapeutic alliance is strengthened in this stage when the physician accepts expressions of the patient’s disappointments, encourages such expressions when they are not forthcoming, and prepares the patient for the future. Such preparations include orienting the patient as to when he or she might seek further treatment (Ursano and Silberman 2002). Solidifying the physician–patient relationship at the end of the treatment can be critical to the patient’s self-esteem and willingness to return if symptoms reappear (Table 2–5).

As a part of the termination process the physician and the patient must review what has been learned, discuss what changes have taken place in the patient and the patient’s life, and acknowledge together the sadness and joy of their leave-taking. The termination involves a mourning process even when treatment has been brief or unpleasant. Of course, when the physician–patient relationship has been rewarding, and both physician and patient are satisfied with what they have accomplished, mourning is more intense and often characterized by a bittersweet sadness.

Treatment Settings

The physician–patient relationship takes place in a variety of treatment settings. These include the private office, community clinic, emergency room, inpatient psychiatric ward, teaching hospital clinic, and general hospital ward. Psychiatrists treating patients in a private office may find that the relative privacy of this setting enhances the early establishment of trust related to confidentiality. In addition, the psychiatrist’s personality is more evident in the private office where personal factors influencing choice of décor, room arrangement, and location play a role. However, in contrast to the hospital or community setting, the private office generally lacks other evidence of the physician’s competence and humanness. In hospital and community settings, when a colleague greets the physician and the patient in the hall, or the physician receives a call for a consultation by a colleague or for a meeting, it indicates to the patient that the physician is qualified, skilled, and humane.

On the other hand, therapeutic work conducted in the community clinic, emergency room, and general hospital ward often requires the psychiatrist and patient to adapt rapidly to meeting one another, assessing the problem, establishing treatment goals, and ensuring the appropriate interventions and follow-up. The importance of protecting the patient’s needs for time, predictability, and structure can run counter to the demands of a busy service and unexpected clinical and administrative requirements. The psychiatrist must stay alert to the patient’s perspective but not all interruptions can be avoided. The patient can be informed and accommodated as much as possible, and any feelings of hurt, disappointment, or anger can be listened for by the physician and responded to empathically. At times, patients, particularly those with borderline personality disorder, may require transfer to another psychiatrist whose schedule can accommodate the patient’s exquisite needs for stability.

The boundaries of confidentiality are necessarily extended in hospital and community settings to include
consultation with other physicians, nursing staff, and often family members (Wise and Rundell 2002). Particular attention must always be given to the patient’s need for and right to respect and privacy. Regardless of the setting, patients receiving medication must be fully informed about the potential risks and benefits of and alternatives to the recommended pharmacological treatment (Kessler 1991). Patients must be educated about the risks and benefits of receiving prescribed treatment and of not receiving treatment. This is an important component of maintaining the physician–patient relationship. Patients who are informed about and involved in decisions about medication respect the physician’s role and interest in their welfare. Psychiatrists must also pay particular attention to the meaning a patient attaches to any prescribed medication, particularly when the time comes to alter or discontinue its use (Ursano et al. 1991).

**Transition Between Inpatient and Outpatient Treatment**

Many psychiatric treatments include the sheltered environment of a hospital for at least some time. The purpose of this environment is to provide the patient with a safe refuge, a moratorium during which stressors are reduced, supportive assistance is provided, and an inner equilibrium is reestablished in the mind and life of the patient. In this situation, the patient is temporarily relieved of some elements of personal responsibility, at least, compared with what is expected of that person in the community. This difference is reflected in the relationship between physician and patient. The change from inpatient to outpatient therapy involves the resumption of a greater degree of autonomy by the patient in the physician–patient dyad. The physician must actively encourage this separation and its hope for the future. This transition is delicate for any therapeutic pair.

So, too, is the extremely delicate situation that occurs when the patient must switch physicians for any reason. This often occurs when a patient leaves the hospital and begins outpatient work with a new therapist. It may also occur in a teaching hospital clinic in which residents rotate annually. Discussing with the patient the skills and abilities of the receiving physician can alleviate much anxiety and foster the new physician–patient relationship. The knowledge that the receiving physician is known and respected by the present physician is a powerful endorsement. In difficult cases, in which the strength of the therapeutic alliance is critical to the stability of the patient, as is seen in some psychotic disorders and with some patients with borderline personality disorder, it may be helpful to hold a joint meeting before the transfer. At this meeting, both the new and the old physicians should be present; the patient can be scheduled for an appointment with the new physician in the same week.

**Managed Care**

Managed care, broadly defined as any care of patients that is not determined solely by the provider, currently focuses on the economic aspects of delivering medical care, with little attention thus far to its potential effects on the physician–patient relationship (Goodman et al. 1992). Discontinuity of care and the creation of unrealistic expectations on the part of patients have been raised as likely deleterious effects on that relationship (Emanuel and Brett 1993). Other issues that can affect the physician–patient relationship include the erosion of confidentiality, shrinkage of the types of reimbursable services, and diminished autonomy of the patient and the physician in medical decision-making. Additionally, many managed care systems dictate a split treatment model, with the psychiatrist prescribing psychopharmacologic treatment and a separate clinician providing psychotherapy. In such a system, there are complicated challenges faced both by clinicians and patients. With neither party in complete control of decisions, the physician–patient relationship can become increasingly adversarial and subservient to external issues such as cost, quality of life, political expediency, and social efficiency (Siegl 1993).

Psychiatrists can best serve their patients by continuing to conduct thorough diagnostic assessments covering the biological, psychological, and social aspects of the patients’ conditions to determine the most effective plan for treatment (Engel 1980). This plan should be openly shared with the patient regardless of whether economic considerations render it infeasible. The psychiatrist and patient may then work together to make the best of what is possible, both aware of the societal and individual factors influencing their actions. (For a more detailed discussion of this topic, see Chapter 5.)

**Health and Illness of the Physician**

Psychiatrists, like all people, become ill, and the illness can affect their ability to work effectively. Reactions of denial, projection, and hopelessness, to name but a few of the possibilities, can distort the psychiatrist’s vision of the patient. The psychiatrist may be blinded to the patients’ suffering, or see it as if it were his or her own or, worse yet, as a hopeless situation. In some instances, a physician who is ill must leave a practice temporarily or permanently, and in that situation therapy enters a late phase in which termination must take place. In some cases, when the onset of illness is devastating, this can be impossible; in other cases termination may have to be rapid. Sometimes, such as when the physician dies suddenly, colleagues must step in to conduct the termination of therapy or the patient’s transfer and transition to another physician (Lasky 1990, Simon 1990).

Another situation that may impact the doctor–patient relationship occurs with the pregnancy of the physician. Patient’s issues about fertility, parenting, loss may arise. Careful discussion and preparation for any planned or anticipated leave may be helpful as well. Referral to a covering physician during this time is helpful.

Depression and grief can also impair the physician’s ability to make use of accurate empathy and medical decision-making. It is important for physicians to stay alert to these influences and seek clinical supervision or consultation to ensure accurate decision-making and a consistent physician–patient relationship. A thoughtful colleague who recognizes the role of depression and grief in the life course can assist in any treatment that is needed and also help to provide a necessary period of clinical supervision or consultation.

**The Physician–Patient Relationship in Specific Populations of Patients**

**Cross-Cultural and Ethnic Issues**

Addressing cross-cultural issues such as race, ethnicity, religion, and gender is vital to the establishment and
maintenance of an effective physician–patient relationship (see Chapter 4). Psychiatry, as practised in the US, generally represents the value orientation of the American middle-class family, emphasizing individualism, scientific rationale, free expression of speech, and tolerance of dissent (Kinzie 1978). Accordingly, therapists may unconsciously make value judgments stemming from their personal cultural perspective without adequate appreciation for the diversity of normal behavior (Ursano and Fullerton 1991). For example, assertiveness may be seen as manipulativeness, stoicism as passivity, religious ritual as compulsion, competence as dominance, unselfishness as masochism, charm as seductiveness, lack of concern with appearance as depression, family orientation as dependency, and homosexuality as perversion. Even similarities in background may create misunderstanding, in that both physician and patient may make unjustified assumptions or fail to explore certain behaviors or symptoms because the reasons for them seem self-evident. Failure to clarify cultural assumptions, whether stemming from differences or similarities in background, may impede the establishment of a trusting therapeutic alliance, making effective treatment unlikely (Cheng and Lo 1991).

Every individual is inevitably like everyone else, like someone else, and like no one else (Kluckhohn and Murray 1953). Thus, every physician–patient relationship involves the individuals, their unique past, and their interpersonal histories (Gabbard 2000). Maintaining a thoughtful awareness of and appreciation for the influence of cross-cultural issues can enrich and empower the physician–patient relationship.

When psychiatrists work with a patient who belongs to or identifies with a particular ethnic or minority group, they are well advised to learn about the culture of the patient and use caution in making assumptions based on stereotypical or popular beliefs. This is true even when the psychiatrist has the same ethnic or minority group background. Other significant cross-cultural factors include gender, sexual orientation, physical appearance, religious background, and personal experience (Comas-Diaz and Jacobsen 1991). Often, asking the patient how an event would be seen or how they would handle a situation may help to avoid making assumptions from the physician’s perspective without adequate appreciation for the diversity of normal behavior and values may be from those of the physician’s world. Maintaining therapeutic neutrality may be difficult and, in some cases, may require the physician to seek consultation (Kleinman 1991).

**Children, Adolescents, and Families**

Establishing an effective physician–patient relationship with children, adolescents, and families is one of the most challenging and rewarding tasks in the practice of psychiatry. Rather than being treated as “little adults,” children and adolescents must be approached with an appreciation for their age-appropriate developmental tasks and needs. When psychiatrists treat this population, they must establish a trusting relationship with both the patient and the parents. Preadolescent children face the psychosocial developmental tasks of establishing trust, autonomy, initiative, and achievement. By understanding the facets of normal childhood development, physicians may help parents understand the nature of their child’s disturbance and work within the family system to establish effective mechanisms for coping and recovery (Angold 2000, Erikson 1950).

Adolescent patients, facing the task of establishing an individual identity, pose particular challenges to the physician–patient relationship. Adolescents can be particularly sensitive to any signals from the physician that their powers of decision, their intelligence, or their perceptions are being ignored. The critical time for engagement with the adolescent is often in the first session, sometimes even in the first few minutes (Katz 1990). Defiance, detachment, and aggression may be anticipated and defused with a steady therapeutic presence grounded in consistent boundaries and open acknowledgment of the adolescent patient’s distress (Colson et al. 1991).

In working with families, physicians in general and psychiatrists in particular must clearly address questions and concerns regarding all aspects of treatment and convey respectful compassion for all members. The therapeutic alliance, or “joining” with the family and patient, requires developing enough of a family consensus that treatment is worth the struggle involved. Taking sides and engaging with individual and family power struggles can be particularly destructive to the physician–patient relationship in families. Rather, it is the physician’s ability to relate to the family as a multifaceted organism, massively interconnected, transcending the sum of its parts, that often allows treatment to progress and, in the best scenarios, allows for growth and understanding to occur (Fleck 1985, Ziegler 1999).

**Terminally Ill Patients**

Terminally ill patients share concerns related to the end of the life cycle. Elderly patients at all levels of health face the developmental task of integrating the various threads of their life into a figurative tapestry that reflects their lifelong feelings, thoughts, values, goals, beliefs, experiences, and relationships and places them into a meaningful perspective. Patients newly diagnosed with a terminal illness such as metastatic cancer or acquired immunodeficiency syndrome may be particularly overwhelmed and initially unable to deal with the demands of their illness, especially if the patient is a younger adult or child. Psychiatrists may enhance the terminally ill patient’s ability to cope by addressing issues related to medical treatment, pharmacotherapy, psychotherapy, involvement of significant others, legal matters, and institutional care (Lederberg and Holland 2000). Patients struggling with spiritual or religious concerns may benefit from a religious consultation, a resource that is frequently unused.

Countertransference feelings ranging from fear to helplessness to rage to despair can assist the therapist greatly in maintaining the physician–patient relationship and ensuring appropriate care. Physicians working with patients with acquired immunodeficiency syndrome must frequently confront their own feelings and attitudes toward homosexuality (McKusick 1988). Issues commonly encountered with disabled patients include inaccurate assumptions about their ability to function fully in all areas of human activity, including sex and vocation. Terminally ill patients may evoke reactions of unwarranted pessimism, thwarting the
physician’s ability to help the patient maximize hope for the quality of whatever time may remain. Patients and their family members often look to their physician for guidance.

**Physicians, Important Persons, and Relatives**

Treating other physicians, important persons, and personal relatives poses significant risks that must be actively addressed within the physician–patient relationship. Patients who are physicians are frequently expected to assume greater responsibility for their care and, if there is evidence of poor compliance, to “know better.” Relinquishing control and acknowledging dependency run counter to the professional development of most physicians, who are accustomed to caring for others and may fear becoming a burden. Furthermore, they may refrain from asking pertinent questions to avoid further embarrassment and humiliation (Lederberg and Holland 2000).

Patients who are important persons or personal relatives pose similar challenges. With these patients and with other physicians, the treating physician may feel insecure and under increased pressure to perform flawlessly. Psychiatrists risk losing their usual assessment benchmarks when making exceptions to standard practice habits in recognition of a patient’s special status. Difficult transferential issues for the physician include managing self-esteem, overidentification with the patient, ethical boundaries, and the potential dilemmas arising from ruptured treatment. Professional identification, awe of celebrity, and personal attachment exert tremendous pressures that can tax even the most seasoned psychiatrist in maintaining a healthy relationship with the patient. The psychiatrist may consult with uninvolved peers and, especially in the case of patients who are relatives, arrange for timely referrals to ensure appropriate treatment (Bridges 1993).

**Conclusion**

The physician–patient relationship is essential to the healing process and is the foundation on which an effective treatment plan may be negotiated, integrating the best of what medical technology and human caring can provide. The centrality of this relationship is particularly true for psychiatric physicians and their patients. In the psychiatrist–patient relationship, empathy, compassion, and hope frequently serve as the major means of alleviating pain and enhancing active participation in all treatment interventions: biological, psychological, and social.

The development of the physician–patient relationship depends on skilled assessment, the development of rapport through empathy, a strong therapeutic alliance, and the effective understanding of transference, countertransference, and defense mechanisms. Current research findings support the purposeful use of common therapy factors, of which the therapeutic alliance is the most powerful, to enhance clinical outcome.

The development of the physician–patient relationship is influenced by numerous factors, including the phase of treatment, the treatment setting, transitions between inpatient and outpatient care, managed care, and changes in the physician’s health. The astute physician is attuned to the needs and characteristics of specific populations of patients, adopting the therapeutic approach that most effectively bridges the gap between physician and patient and leads to a healing relationship.

Section 1 • Approaches to the Patient

The interview is the principal means of assessment in clinical psychiatry. Despite major advances in neuroimaging and neurochemistry, there are no laboratory procedures as informative as observing, listening to, and interacting with the patient, and none as yet are more than supplementary to the information gathered by the psychiatric interview. This chapter deals with the interview as a means of assessing the patient and developing an initial treatment plan in clinical situations.

Psychiatric interviews are analogous to the history and physical in a general medical assessment, and they share the major features of other types of medical interviews (Mackinnon and Yudofsky 1986); they systematically survey subjective and objective aspects of illness and generate a differential diagnosis and plan for further evaluation and treatment. They differ from other medical interviews in the wide range of biological and psychosocial data, which they must take into account, and in their attention to the emotional reactions of the patient and the process of interaction between the patient and the interviewer. The nature of the interaction is informative diagnostically and is a means of building rapport and eliciting the patient’s cooperation, which is especially important in psychiatry (Reiser and Schroder 1980). The style and content of a psychiatric interview are necessarily shaped by the interviewer’s theory of psychopathology (Lazare 1973). Thus, a biological theory of illness leads to an emphasis on signs, symptoms, and course of illness; a psychodynamic theory dictates a focus on motivations, attitudes, feelings, and personal interactions; a behavioral viewpoint looks at antecedents and consequences of symptoms or maladaptive behaviors. In past times, when these and other theories competed for theoretical primacy, an interviewer might have viewed exploration from a particular single perspective as adequate. However, modern psychiatry views these perspectives as complementary rather than mutually exclusive and recognizes the contributions of biological, intrapsychic, social, and environmental factors to human behavior and its disorders (Leigh and Reiser 1992b). The interviewer, therefore, faces the task of understanding each of these dimensions, adequately surveying them in the interview, and making informed judgments about their relative importance and treatment implications (Shea 1990).

The written psychiatric database, the mental organization which the interviewer maintains during the interview, and the structure of the interview itself may differ considerably from one another. The written psychiatric database is an orderly exposition of information gathered in the interview, presented in a relatively fixed format. The mental organization of the interviewer consists of questions and tentative hypotheses. It evolves flexibly over the course of the interview and is determined by the goals of the interview and emerging information that indicates needed areas of focus (Lazare 1976).

The third structure is that of the interview itself. While guided by general principles of interviewing, this structure is the most flexible of the three, being determined not only by the purpose of the interview and the type of problem that the patient presents, but also by the patient’s mode of communication and style of interaction with the interviewer. Thus, the interviewer must hold his/her own structure in mind while responding flexibly to the patient.

Goals of the Psychiatric Interview
The interviewer may be thought of as seeking the answers to several basic questions about the patient and the presenting problems (American Psychiatric Association 2006). These questions provide the mental framework of the interview (although not its explicit form). They begin by triaging the patient’s problem into broad categories of type and severity...

and progress to inquiry about details in each salient area. Table 3–1 presents the questions that the interview addresses and the implications of each for understanding and treating the patient.

The answers to the questions in Table 3–1 are presented here in greater detail.

**Does the Patient Have a Psychiatric Disorder?**

This is the most basic question which the psychiatrist is called upon to answer and determines whether or not there is any need for further psychiatric assessment or treatment.

**How Severe Is the Illness?**

The answer to this question determines the necessary level of treatment, ranging from hospitalization with close observation to infrequent outpatient visits. The main determinants of severity are dangerousness to self and others and impairment in ability to care for oneself and function in social and occupational roles.

**What Is the Diagnosis?**

In psychiatry, as in the rest of medicine, descriptive information about signs, symptoms, and course over time is used to assign a diagnosis to the presenting problem. Not all psychiatric diagnoses have well-established validity, but most convey knowledge of prognosis, comorbidity, treatment response, occurrence in family members, or associated biological or psychological findings (Tischler 1987). Even in the case of poorly understood entities, our present system of diagnosis using specific criteria maximizes uniformity in the description and naming of psychiatric disorders.

One important implication of diagnoses is whether there may be reduced plasticity of brain functioning due to anatomical or physiological abnormalities. Symptoms, deficits, and behaviors that stem from such abnormalities vary less in response to environmental and motivational factors than those behaviors that arise in the context of normal brain function. For example, mood swings in a patient with bipolar disorder, a condition for which there is strong evidence of a biological–genetic etiology, typically recur at regular time intervals, often independently of the patient’s life situation. By contrast, mood swings in a patient with narcissistic personality disorder are much more likely to be triggered by interactions with other people. Furthermore, when brain function is impaired, biological treatments are more likely to be necessary, and verbal, interpersonal, or environmental interventions are less likely to be sufficient. Thus, the likelihood of altered brain function has major implications for understanding and treating the patient’s problems.

Although the question of brain abnormalities is basic to psychiatric triaging, we do not yet have a clear-cut biological etiology for any disorder outside of those historically classified as “organic.” Standard laboratory studies (such as brain imaging or electroencephalography) are not generally diagnostic of psychopathology; however, there is research-based evidence of altered brain function in many psychiatric disorders. Table 3–2 presents an overview of the current state of knowledge of brain abnormalities in psychiatric disorders, along with known responses to biological and psychosocial treatments.

**What Is the Patient’s Baseline Level of Functioning?**

Determining what the patient has been like in his/her best or most usual state is a vital part of the assessment. This information allows the interviewer to gauge when the patient became ill, and how he/she is different when ill versus well. Environmental, biological, and psychological factors that contribute to low baseline levels of functioning may also predispose a patient to the development of psychiatric disorders. Thus, information about baseline functioning provides clues about the patient’s areas of vulnerability to future illness as well as his/her capacity to benefit from treatment. It is also an important guide to realistic goals and expectations for such treatment. Table 3–3 presents major components of functioning with examples of elements of each.

**What Environmental Factors Contribute to the Disorder?**

Environmental contributions to the presenting problem are factors external to the patient. They may be acute events that precipitate illness or long-standing factors that increase

General vulnerability. Loss, change, and traumatic events are very common acute precipitants (Paykel 1978). Long-standing environmental stressors may predispose the patient to the development of illness and may also worsen the outlook for recovery.

It is important to identify adverse environmental influences that can be modified and to help the patient or family make necessary changes. For example, a patient with recurrent paranoid psychosis needed yearly hospitalization as long as she worked in an office with many other people. Once she was helped to find work that she could do in her own home, she no longer suffered severe relapses. However, even irreversible precipitants, such as death of a loved one, must be identified and dealt with in the treatment plan.

What Biological Factors Contribute to the Disorder?

Biological factors may contribute to psychiatric disorders directly by their effects on the central nervous system and indirectly through the effects of pain, disability, or social stigma. Thus, biological factors must be assessed through both the psychiatric history and diagnosis, and the general medical history.

Biological factors affecting the central nervous system may be genetic, prenatal, perinatal, or postnatal. There is strong evidence of genetic contributions to schizophrenia, bipolar disorder, and alcoholism, among others (Carpenter and Buchanan 1994, Jorgensen et al. 1996, Kluft and Fine 1993, Sullivan 2005). Conditions such as maternal substance abuse or intrauterine infections may affect fetal brain development; birth complications may cause cerebral hypoxia with resultant brain damage. In postnatal life, the entire range of diseases that affect the brain may alter mental function and behavior, as may exposure to toxins at work, in the environment, and through substance abuse. In addition, medical conditions that do not directly affect brain functioning may have profound effects on the patient’s state of mind and behavior.

Clinical Vignette 1

A 30-year-old married woman suffers from chronic low mood and lack of enjoyment of life. She is highly dependent on her husband for practical and emotional support, although she frequently flies into rages at him, feeling that he is cold and uncaring. She has had a series of secretarial jobs which she begins enthusiastically, but soon comes to feel that her employers are highly critical and belittling, whereupon she resigns. Her friendships are limited to people with whom she can have very special, exclusive relationships. She deals poorly with change or loss, which frequently triggers episodes of acute dysfunction. When a friend is not sufficiently available to her, she feels betrayed and worthless, her mood plummets, she becomes lethargic, has eating binges, and is unable to work or pursue her usual routine for up to weeks at a time.

What Psychological Factors Contribute to the Disorder?

Psychological factors are mental traits that the patient brings to life situations. While they interact with social and environmental factors, they are intrinsic to the individual, and not readily changed by outside influences.

Psychological factors predisposing to illness include both general and focal deficits in coping adaptability. General deficits encompass the entire range of ego functioning, including poor reality testing, rigid or maladaptive psychological defense mechanisms, low ability to tolerate and contain affects, impulsivity, poorly formed or unstable sense of self, low self-esteem, and hostile, distant, or dependent relationships with others (Valliant 1977). Patients with such deficits generally meet diagnostic criteria for one or more personality disorders and are at increased risk for episodes of acute psychiatric illness. An example of general deficits in psychological functioning is illustrated by the following case.

Focal psychological issues may also contribute to mental disorders. These issues, which typically involve conflicts between opposing motivations, may affect the patient in certain specific areas of function or life situations, leaving other broad areas of function intact (Nemiah 1961a). Such conflicts are most likely to cause maladaptive behaviors or symptoms when the patient is not clearly aware of them.

The meaning of an event in the context of the patient’s life course is another focal issue that may contribute to illness.

What Is the Patient’s Motivation and Capacity for Treatment?

Whatever the physician’s view of the presenting problem, the patient’s wishes and capacities are a major determinant of treatment choice (Lazare et al. 1975). Some patients seek relief of symptoms; some wish to change their behavior or the nature of their relationships; some want to understand themselves better. Patients may wish to talk or to receive medication or instructions.

The patient’s capacity for treatment must also be considered in the treatment plan. For example, a patient with schizophrenia may agree to medication but be too disorganized to take it reliably without help. Suitability for exploratory psychotherapy depends upon such factors as the ability to observe oneself, tolerate unpleasant affects, and establish and maintain a working relationship with the therapist (Strupp and Binder 1984). Such factors must be evaluated in the interview.

The Psychiatric Database

The body of information to be gathered from the interview may be termed the psychiatric database (Tables 3–2 to 3–4). It is a variable set of data: either very specific or general, mainly limited to the present state or focused on early life, dominated by neurological questions or inquiry into relationships. To avoid setting the impossible task of learning everything about every patient, one must consider certain factors that modify the required database.

Whose questions are to be answered—the patient’s concern about himself, a family or friend’s concern about him, another physician’s diagnostic dilemma, a civil authority’s need to safeguard the public, or a research protocol
Identifying Data

- Any previous psychiatric treatment
- History of suicide attempts
- Functioning problems secondary to psychiatric symptoms
- Alcohol/drug abuse

Personal History

- Educational level
- Ever married/committed relationship
- Work history
- Means of support
- Living situation

Chief Complaint

The chief complaint is the patient’s responses to the question, “What brings you to see me/to the hospital today?” or some variant. It is usually quoted verbatim, placed within quotation marks, and should be no more than one or two sentences.

Even if the patient is very disorganized or hostile, quoting his response can give an immediate sense of where the patient is as the interview begins. If the patient responds with an expletive, or a totally irrelevant remark, the reader of the database is immediately informed about how the rest of the information may be distorted. In such cases, or if the patient gives no response, a brief statement of how the patient came to be evaluated should be made and enclosed in parentheses.

History of the Present Illness

Minimum Essential Database. The present illness history should begin with a brief description of the major symptoms that brought the patient to psychiatric attention. The most troubling symptoms should be detailed initially; later, a more thorough review will be stated. At a minimum, the approximate time since the patient was last at his/her baseline level of functioning, and in what way he/she is different from that now, should be described, along with any known stressors, the sequence of symptom development, and the beneficial or deleterious effects of interventions, included.

How far back in a patient’s history to go, especially when he/she has chronic psychiatric illness, is sometimes problematic. In patients who have required repeated hospitalization, a summary of events since last discharge (if within 6 months) or last stable baseline is indicated. It is rare that more than 6 months of history be included in the

requirement? Who will have access to the data gathered and under what circumstances? What is the setting of the interview? Priorities in an emergency room differ from those in an office setting (Meyers and Stein 2000). Is the interview to be the first session of a psychotherapy regimen, or is it a one-time-only evaluation? What is the nature of the pathology? For example, negative responses regarding the presence of major psychotic symptoms, coupled with a history of good occupational function, will generally preclude a detailed inventory of psychotic features. A missed orientation or memory question will require careful cognitive testing. Patients with personality disorder symptoms warrant careful attention to the history of significant relationships (Nurnberg et al. 1991), work history, and the feelings evoked in the interviewer during the evaluation process. The database should be expanded in areas of diagnostic concern to support or rule out particular syndromes. The amount and nature of the data obtained is also, of necessity limited, by the patient’s ability to communicate and his cooperativeness.

Database Components

Identifying Data

This information establishes the patient’s identity, especially for the purpose of obtaining past history from other contacts, when necessary, as well as to fix his/her position in society. The patient’s name should be recorded, along with any nickname or alternative names he/she may have been known by in the past. This is important for women who might have been treated previously under a maiden name, or a patient who has had legal entanglements and so has adopted aliases.

Date of birth, or at least age, and race are other essential parts of every person’s database. A number of different classifications for race exist, as well as different terms and controversies (Porter 1993). In the United States and Canada, the categories of white, black (or African-American), Asian, Native American, and others are generally accepted. The additional modifier of ethnicity, especially Hispanic/non-Hispanic, is becoming more widely used. If a patient is a member of a particular subculture based on ethnicity, country of origin, or religious affiliation, it may be noted here.

A traditional part of the identifying data is a reference to the patient’s civil status: single, married, separated, divorced, or widowed. The evolution of relationship patterns over the last two decades, with less frequent formalization of relationships, has made classification more difficult (Ishii-Kuntz and Tallman 1991), especially in the case of homosexual patients, whose relationships may have different degrees of recognition and terms depending upon the particular jurisdiction.

The patient’s social security number (or other national ID number) can be a very useful bit of data when seeking information from other institutions. It is sometimes set aside for particular protection due to the danger of identity theft. In most cases, it is assumed that the informant (supplier of the history) is the patient. If other sources are used, and especially if the patient is not the primary informant, this should be noted at the beginning of the database.

Chief Complaint

The chief complaint is the patient’s responses to the question, “What brings you to see me/to the hospital today?” or some variant. It is usually quoted verbatim, placed within quotation marks, and should be no more than one or two sentences.

Even if the patient is very disorganized or hostile, quoting his response can give an immediate sense of where the patient is as the interview begins. If the patient responds with an expletive, or a totally irrelevant remark, the reader of the database is immediately informed about how the rest of the information may be distorted. In such cases, or if the patient gives no response, a brief statement of how the patient came to be evaluated should be made and enclosed in parentheses.

Minimum Essential Database. The present illness history should begin with a brief description of the major symptoms that brought the patient to psychiatric attention. The most troubling symptoms should be detailed initially; later, a more thorough review will be stated. At a minimum, the approximate time since the patient was last at his/her baseline level of functioning, and in what way he/she is different from that now, should be described, along with any known stressors, the sequence of symptom development, and the beneficial or deleterious effects of interventions, included.

How far back in a patient’s history to go, especially when he/she has chronic psychiatric illness, is sometimes problematic. In patients who have required repeated hospitalization, a summary of events since last discharge (if within 6 months) or last stable baseline is indicated. It is rare that more than 6 months of history be included in the
history of the present illness, and detailed history is more commonly given on the past month.

**Expanded Database.** A more expanded description of the history of the present illness would include events in a patient’s life at the onset of symptoms, as well as exactly how the symptoms have affected the patient’s occupational functioning and important relationships. Any concurrent medical illness symptoms, medication usage (and particularly changes), alterations in the sleep–wake cycle, appetite disturbances, and eating patterns should be noted; significant negative findings should also be remarked upon.

**Past Psychiatric History**

**Minimum Essential Database.** Most of the major psychiatric illnesses are chronic in nature. For this reason, often patients have had previous episodes of illness with or without treatment. New onset of symptoms, without any previous psychiatric history, becomes increasingly important with advancing age in terms of diagnostic categories to be considered. At a minimum, the presence or absence of past psychiatric symptomatology should be recorded, along with psychiatric interventions taken and the result of such interventions. An explicit statement about past suicide and homicide attempts should be included.

**Expanded Database.** A more detailed history would include names and places of psychiatric treatment, dosages of medications used, and time course of response. The type of psychotherapy, the patient’s feelings about former therapists, his/her compliance with treatment as well as circumstances of termination are also important. Note what the patient has learned about the biological and psychological factors predisposing him/her to illness, and whether there were precipitating events.

**Past Medical History**

**Minimum Essential Database.** In any clinical assessment, it is important to know how a patient’s general health status has been. In particular, any current medical illness and treatment should be noted (Slaby and Andrew 1987), along with any major past illness requiring hospitalization. Previous endocrine or neurological illness are of particular pertinence (Flomenbaum and Altman 1985).

**Expanded Database.** An expanded database could well include significant childhood illnesses, how these were handled by the patient and his/her family, and therefore the degree to which the patient was able to develop a sense of comfort and security about his/her physical well-being. Illnesses later in life should be assessed for the degree of regression produced. The amount of time a patient has had to take off work, how well he/she was able to follow a regimen of medical care, and his/her relationship with the family physician or treating specialist can all be useful in predicting future response to treatment. A careful past medical history can also at times bring to light a suicide attempt, substance abuse, or dangerously careless behavior, which might not be obtained any other way.

**Family History**

**Minimum Essential Database.** Given the evidence for familial, genetic factors in so many psychiatric conditions, noting the presence of mental illness in biological relatives of the patient is a necessary part of any database (Hammen et al. 1987). It is important to specify during questioning the degree of family to be considered—usually to the second degree: aunts, uncles, cousins, and grandparents, as well as parents, siblings, and children.

**Expanded Database.** A history of familial medical illness is a useful part of an expanded database. A genogram (pedigree), including known family members with dates and causes of death and other known chronic illnesses, is helpful. Questioning about causes of death will also occasionally bring out hidden psychiatric illness, for example, sudden, unexpected deaths that were likely suicides or illness secondary to substance abuse.

**Personal History**

**Minimum Essential Database.** Recording the story of a person’s life can be a daunting undertaking and is often where a database can expand dramatically. At a minimum, this part of the history should include where a patient was born and raised, and in what circumstances—intact family, number of siblings, and degree of material comfort. Note how far the patient went in school, how he/she did there, and what his/her occupational functioning has been. If he/she is not working, why not? Has the patient ever been involved in criminal activity, and with what consequences? Has the patient ever married or been involved in a committed relationship? Are there any children? What is his/her current source of support? Does he/she live alone or with someone? Has he/she ever used alcohol or other drugs to excess and is there current use? Has he/she ever been physically or sexually abused or been the victim of some other trauma?

**Expanded Database.** An expanded database can include a great deal of material beginning even prior to the patient’s conception. What follows is an outline of the kind of data that may be gathered, along with an organizational framework.

**Family of Origin**

Were parents married or in committed relationships? Personality and significant events in life of mother, father, or other significant caregiver. Siblings: How many? Their ages, significant life events, personality, and relationship to patient. Who else shared the household with the family?

**Prenatal and Perinatal**

Was the pregnancy planned? Quality of prenatal care; mother’s and father’s response to pregnancy. Illness, medication or substance abuse, smoking, and trauma during pregnancy; labor—induced or spontaneous? Week’s gestation, difficulty of delivery, vaginal or caesar- ean section. Presence of jaundice at birth, birth weight, and Apgar score. Baby went home with mother or stayed on in hospital.

**Early Childhood**

Developmental milestones: smiling, sitting, standing, walking, talking, and type of feeding—food allergies or intolerance.
Consistency of caregiving: interruptions by illness and birth of siblings.
Reaction to weaning, toilet training, and maternal separation.
Earliest memories: problematic behavior (tantrums, bed-wetting, hair-pulling, or nail-biting).
Temperament (shy, overactive, outgoing, and fussy).
Sleep problems: insomnia, nightmares, enuresis, and parasomnias.

Later Childhood
Early school experiences: evidence of separation anxiety.
Behavioral problems at home or school: fire-setting, bed-wetting, aggressiveness toward others, cruelty to animals, and nightmares.
Developmental milestones: learning to read and write.
Relationships with other children and family: any loss or trauma.
Reaction to illness.

Adolescence
School performance: ever in special classes?
Athletic abilities and participation in sports.
Evidence of gender identity concerns: overly “feminine” or “masculine” in appearance/behavior, or perception by peers.
Ever run away? Able to be left alone and assume responsibility.
Age onset of puberty (menarche or nocturnal emissions) and reaction to puberty.

Identity
Sexual preference and gender identity and religious affiliation (same as parents?).
Career goals: ethnic identification.

Sexual History
Early sexual teaching: earliest sexual experiences, experience of being sexually abused, and attitudes toward sexual behavior.
Dating history and precautions taken to prevent sexually transmitted diseases and/or pregnancy.
Episodes of impotence and reaction.
Masturbating patterns and fantasies.
Preoccupation with particular sexual practices, current sexual functioning, length of significant relationships, and ages of partners.

Adulthood
Age at which left home and level of educational attainments.
Employment history, relationships with supervisors and peers at work, and reasons for job change.
History of significant relationships, including duration, typical roles in relationships, and patterns of conflict: marital history, legal entanglements and criminal history, both covert and detected, ever victim or perpetrator of violence.
Major medical illness as adult.
Participation in community affairs.
Financial status: own or rent home and stability of living situation.
Ever on disability or public assistance?

Current family structure, reaction to losses of missing members (parents and siblings), if applicable.
Substance abuse history.

Mental Status Examination
It can be helpful to conceptualize the recording of the mental status examination as a progression. One begins with a snapshot: what can be gained from a cursory visual examination, without any movement or interaction—appearance and affect. Next, motion is added: behavior. Then comes sound: the patient’s speech, though initially only as sound. The ideas being expressed come next: the thought process and content, perception, cognition, insight, and judgment. Table 3–5 gives a summary of areas to be commented on, along with common terms.

At every level of the mental status examination, preference should be given for explicit description over jargon. Stating that a patient is delusional is less helpful than describing the patient as believing that his/her neighbors are pumping poisonous gases into his/her bedroom while the patient sleeps.

(continues)
Conduct of the Interview

Factors Which Affect the Interview
A skillful interview will not necessarily yield all the relevant information but will make the most of the opportunities in a clinical situation, given the limitations that both the patient and the interviewer bring. Factors that influence the development of an alliance and the amount that can be learned in the interview include the following:

The Patient’s Physical or Emotional Distress
Patients who are in acute distress either from physical discomfort or from emotional factors, such as severe depression or anxiety, will be limited in their motivation and ability to interact with the interviewer. The interviewer may be able to enhance communication by addressing the patient’s discomfort in a supportive manner. However, he/she must also recognize times when the patient’s discomfort necessitates a more limited interview.

The Cognitive Capacities of the Patient
Patients who are demented, retarded, disorganized, thought disordered, amnesic, aphasic, or otherwise impaired in intellectual or cognitive capacity have biologically based deficits that limit the amount of information they can convey.

The Emotionally Based Biases of the Patient
Patients bring to the interview a wide variety of preconceptions, expectations, and tendencies toward distortion, which influence how they view and relate to the interviewer. Such biases are commonly referred to as transference because they frequently can be understood as arising from interactions with important figures in childhood, such as parents, which then color perceptions of others during adult life (Nemiah 1961b). Transferential biases may be positive or negative. Thus, even before the start of the interview, one patient may be primed to view the doctor as a wise and kindly healer, while another will be predisposed to see him/her as an exploitative charlatan. Clearly, such biases affect the amount of openness and trust that the patient brings to the interview and the quality of information he/she provides.

The Emotionally Based Biases of the Interviewer
The interviewer, like the patient, may have feelings stirred up by the interaction. The interviewer’s emotional reactions to the patient can be an invaluable asset in assessment if he/she can be conscious of them and reflect on their causes. For example, an interviewer finds himself/herself becoming increasingly annoyed at a highly polite patient. On reflection, he/she realizes that the politeness serves to rebuff him/her attempts to establish a warmer, more spontaneous relationship, and is a manifestation of the patient’s underlying hostile attitude.

When the interviewer is unable to monitor and examine his/her emotional reactions, they are more likely to impede rather than enhance understanding of the patient. This is most likely to happen when emotional reactions are driven more by the interviewer’s own biases than by the patient’s behavior. Such reactions are referred to as the interviewer’s countertransference (Mackinnon and Michels 2006). In the example cited in the previous paragraph, the interviewer might inaccurately perceive a polite patient as rigid and hostile due to unconscious biases (countertransference) based on his/her relationship with his/her own rigidly polite parent. The entire range of countertransferralent interviewer attitudes toward the patient, from aversion to infatuation, might similarly bias judgment.

Situational Factors
Patients’ attitudes toward the interview will be strongly influenced by the situation in which the consultation arises. Some patients decide for themselves that they need treatment, while others come reluctantly, under pressure from others. Patients who are being evaluated for disability or in connection with a lawsuit may feel a need to prove that they are ill, while those being evaluated for civil commitment or at the insistence of family members may need to prove that they are well. Similarly, a patient’s past history of relationships with psychiatrists or with health professionals in general is likely to color his/her attitude toward the interviewer.

The interviewer may also be affected by situational factors. For example, pressure of time in a busy emergency service may influence the interviewer to omit important areas of inquiry and reach premature closure; the experience of a recent patient suicide may bias the interviewer toward overestimation of risk in someone with suicidal thoughts.
As with countertransference reactions, it is important for the interviewer to minimize distortions due to situational factors by being as aware of them as possible.

Racial, Ethnic, and Cultural Factors
The degree of racial, ethnic, cultural, and socioeconomic similarity between the patient and the interviewer can influence the course and outcome of the interview in many ways. It may affect the level of rapport between patient and interviewer, the way both view the demands of the situation, the way they interpret each other's verbal and nonverbal communications, and the meaning the interviewer assigns to the patient's statements and behaviors (Gaw 1993). Not only racial or cultural prejudice but also well-intentioned ignorance can interfere with communication and accurate assessment.

Some cultures, for example, place a higher value on politeness and respect for authority than does Western culture. A patient from such a background might be reluctant to correct or disagree with the interviewer's statements even when they are erroneous. The interviewer might not suspect that he/she was hearing distorted information or conversely, might see the patient as pathologically inhibited or unemotional. Many non-Western cultures place a higher value on family solidarity than on individuality (Barrett 2006). Pressing a patient from such a culture to report angry feelings toward family members might raise his/her anxiety, decrease rapport with the interviewer, and produce defensive distortions in the material.

General Features of Psychiatric Interviews
Setting
The ideal interview setting is one that provides a pleasant atmosphere and is reasonably comfortable, private, and free from outside distractions. Such a setting not only provides the physical necessities for an interview but also conveys to the patient that he/she will be well cared for and safe. Providing such a setting may pose special problems in certain interviewing situations. For example, it may be necessary to interview highly agitated patients in the presence of security personnel; interviewers on medical–surgical units must pay special attention to the patient's comfort and privacy.

Verbal Communication
Verbal communication may be straightforward imparting of information: “Every year around November, I begin to lose interest in everything and my energy gets very low.” However, patients may convey information indirectly through metaphor or use words for noninformational purposes, such as to express or contain emotions or to create an impact on the interviewer.

In metaphorical language, one idea is represented by another with which it shares some features. For example, when asked how she gets along with her daughter-in-law, a woman replies, “I can never visit their house because she always likes to keep the thermostat down. It’s never as warm as I need.” Such a reply suggests that the woman may not feel “warmly” accepted and welcomed by her son's wife. Metaphor may also use the body to represent ideas or feelings. A man who proved to meet the diagnostic criteria for major depressive disorder described his mood as “OK” but complained that his life was being ruined by constant aching in his chest for which the doctors could find no cause.

In this instance, the pain of depression was experienced and described metaphorically as a somatic symptom.

Language may be used to express emotions directly (“I'm afraid of you and I don’t want to talk to you”), but more often is used indirectly by influencing the process of the interview (Bernstein and Berstein 1985). Patients may shift topics, make offhand remarks or jokes, ask questions, and compliment or belittle the interviewer as a way of expressing feelings. The process of the interview frequently expresses the patient’s feelings about his/her immediate situation or interaction with the interviewer (Malan 1995). For example, a woman being evaluated for depression and anxiety suddenly said, “I was just wondering doctor, do you have any children?” The further course of the interview revealed that she was terrified of being committed to a hospital and abandoned. The question was an attempt to establish whether the interviewer was a good parent and therefore safe as a caretaker for her.

Language may also be used in the service of psychological defense mechanisms to contain rather than express emotions (Freud 1946). For example, a young man with generalized anxiety was asked whether he was sexually active. He replied by talking at length about how all the women he knew at college were either unappealing or attached to other men. Further discussion revealed that he developed severe symptoms of anxiety whenever he was with a woman to whom he felt sexually attracted. His initial reply represented an automatic, verbal mechanism (in this case, a rationalization) for keeping the anxiety out of awareness.

Another form of process communication is the use of language to make an impact on the interviewer (Casement 1985). A statement such as “if you can’t help me I’m going to kill myself” might convey suicidal intent, but may also serve to stir up feelings of concern and involvement in the interviewer. Similarly, the patient who says, “Dr. X really understood me, but he was much older and more experienced than you are,” may be feeling vulnerable and ashamed, and unconsciously trying to induce similar feelings in the interviewer. When language is used in this way, the interviewer's subjective reaction may be the best clue to the underlying feelings and motivations of the patient.

Nonverbal Communication
Emotions and attitudes are communicated nonverbally through facial expressions, gestures, body position, movements of the hands, arms, legs, and feet, interpersonal distance, dress and grooming, and speech prosody (Knapp 1978). Some nonverbal communications such as gestures are almost always conscious and deliberate, while others often occur automatically outside one’s awareness. The latter type are particularly important to observe during an interview because they may convey messages entirely separate from or even contradictory to what is being said.

Facial expression, body position, tone of voice, and speech emphasis are universal in the way they convey meaning (Ekman et al. 1972). The interviewer will automatically decode these signals but may ignore the message due to countertransference or social pressure from the patient. For example, a patient may say, “I feel very comfortable with you, doctor,” but sit stiffly upright and maintain a rigidly fixed smile, conveying a strong nonverbal message of
tension and mistrust. The nonverbal message may be missed if, for example, the interviewer has a strong need to be liked by the patient. Another patient denies angry feelings while sitting with a tightly clenched fist. The interviewer may unconsciously collude with the patient’s need to avoid his/her anger by ignoring the body language.

As with any medical examination, observation of nonverbal behavior may provide important diagnostic information. For example, a leaden body posture may indicate depression, movements of the foot may arise from anxiety or tardive dyskinesia, and sudden turning of the head and eyes may suggest hallucinations.

Nonverbal communication proceeds in both directions, and the nonverbal messages of the interviewer are likely to have a considerable effect on the patient. Thus, the interviewer who sits back in his/her chair and looks down at his/her notes communicates less interest and involvement than one who sits upright and makes eye contact. Similarly, an interviewer who gives a weak handshake and sits behind a desk or far across the room from the patient will communicate a sense of distance, which may interfere with establishing rapport. It is important that the interviewer be aware of his/her own nonverbal messages and adapt them to the needs of the patient.

Listening and Observation

The complexity of communication in the psychiatric interview is mirrored by the complexity of listening (Luborsky 1984). The interviewer must remain open to literal and metaphorical messages from the patient, the impact the patient is trying to make, and the degree to which nonverbal communication complements or contradicts what is being said. Doing this optimally requires that the interviewer also be able to listen to his/her own mental processes throughout the interview, including both thoughts and emotional reactions. Listening of this kind depends upon having a certain level of comfort, confidence, and space to reflect and may be very difficult when the patient is hostile, agitated, demanding, or treating the interviewer as “the other person” (Barrett-Lennard 1981). For example, in listening to a man talk about the death of his wife, the interviewer may allow himself/herself to resonate empathetically with the patient’s feelings of loneliness and desolation. Based on this resonance, he/she might respond, “After a loss like that, it feels as if the world is completely empty.”

As a mode of listening, empathy is an important way of understanding the patient; as a mode of response, it is important in building rapport and alliance. Patients who feel great emotional distance from the interviewer may make empathic understanding difficult or impossible. Thus, the interviewer’s inability to empathize may itself be a clue to the patient’s state of mind.

Structure of the Interview

The overall structure of the psychiatric interview is generally one of reconnaissance and detailed inquiry (Sullivan 1970). In reconnaissance phases, the interviewer inquires about broad areas of symptomatology, functioning, or life course: “Have you ever had long periods when you felt very low in mood?” “How have you been getting along at work?” “Tell me what you did between high school and when you got married...” In responding to such questions, patients may give the interviewer leads, which then must be pursued with more detailed questioning. Leads may include references to symptoms, difficulty in functioning, interpersonal problems, ideas, states of feeling, or stressful life events. Each such lead raises questions about the nature of the underlying problem, and the interviewer must attempt to gather enough detailed information to answer these questions. Reliance on yes or no “gate questions” to rule out areas of pathology has been shown to increase the risk of missing important information. This risk may be minimized by asking about important areas in several ways (Barber et al. 2001).

In general, the initial reconnaissance consists of asking how the patient comes to treatment at this particular time. This is done by asking an open-ended question, such as “what brings you to see me today?” or “how did you come to be in the hospital right now?” A well-organized and cooperative patient may spontaneously provide most of the needed information, with little intervention from the interviewer. However, the patient may reveal deficits in thought process, memory, or ability to communicate, which dictate more structured and narrowly focused questioning.

The patient’s emotional state and attitude may also impede a smooth flow of information. For example, if the
patient shows evidence of anxiety, hostility, suspiciousness, or indifference, the interviewer must first build a working alliance before trying to collect information. This usually requires acknowledging the emotions that the patient presents, helping the patient to express his/her feelings and related thoughts, and discussing these concerns in an accepting and empathic manner (Strean 1985). As new areas of content open up, the interviewer must continue to attend to the patient's reactions, both verbal and nonverbal, and to identify and address resistance to open communication.

Setting an appropriate level of structure is an important aspect of psychiatric interviewing. Psychiatric patients may spontaneously report a low number of symptoms, and initial diagnostic impressions may be misleading (Herran et al. 2001). Over the past two decades, a variety of structured interview formats have been developed for psychiatric assessment (Spitzer et al. 1978, Wiens 1990). In these interviews, the organization, content areas, and, to varying degrees, wording of the questions are standardized; vague, overly complex, leading or biased, and judgmental questions are eliminated, as is variability in the attention given to different areas of content. The major benefits of such interviews are that they ensure complete coverage of the specified areas and greatly increase the reliability of information gathered and diagnostic judgments. In addition, formats that completely specify the wording of questions can be administered by less highly trained interviewers or even as patient self-reports.

The disadvantages of highly structured interviews are that they diminish the ability to respond flexibly to the patient and preclude exploration of any areas not specified in the format (Groth-Marnat 2003). They are therefore used to best advantage for interviews with focused goals. For example, such interviews may aim to survey certain DSM-IV-TR Axis I disorders, assess the type and degree of substance abuse, or delineate the psychological and behavioral consequences of a traumatic event. They are less useful in a general psychiatric assessment where the scope and focus of the interview cannot be preordained.

In the usual clinical situation, while the interviewer may have a standardized general plan of approach, he/she must adapt the degree of structure to the individual patient. Open-ended, nonDirective questions derive from the psychoanalytic tradition. They are most useful for eliciting and following emotionally salient themes in the patient's life story and interpersonal history. Focused, highly structured questioning derives from the medical/descriptive tradition and is most useful for delineating the scope and evolution of pathological signs and symptoms. In general, one uses the least amount of structure needed to maintain a good flow of communication and cover the necessary topic areas.

**Phases of the Interview**

The typical interview comprises an opening, middle, and closing phase. In the opening phase, the interviewer and patient are introduced, and the purposes and procedures of the interview are set. It is generally useful for the interviewer to begin by summarizing what he/she already knows about the patient and proceeding to the patient's own account of the situation. For example, the interviewer may say, “Dr. Smith has told me that you have had several episodes of depression in the past, and now you may be going into another one,” or “I understand that you were brought in by the police because you were threatening people on the street. What do you think is happening with you?” or “when we spoke on the phone you said you thought your marriage was in trouble. What has been going wrong?” Such an approach orients the patient and sets a collaborative tone.

The opening phase may also include clarification of what the patient hopes to get from the consultation. Patients may sometimes state this explicitly, but often do not, and the interviewer should not assume that his/her goals are the same as the patient's (Lazare et al. 1975). A question such as “how were you hoping I could help you with the problem you have told me about?” invites the patient to formulate and express his/her request and avoids situations in which the patient and interviewer work at cross-purposes. The interviewer must also be explicit about his/her own goals and the extent to which they fit with the patient's expectations. This is especially important when the interests of a third party, such as an employer, a family member, or a court of law, is involved.

The middle phase of the interview consists of assessing the major issues in the case and filling in enough detail to answer the salient questions and construct a working formulation. Most of the work of determining the relative importance of biological, psychological, environmental, and sociocultural contributions to the problem is done during this phase. The patient's attitudes and transference perceptions are also monitored during this phase, so that the interviewer can recognize and address barriers to communication and collaboration.

When appropriate, formal aspects of the mental status examination are performed during the middle phase of the interview. While most of the mental status evaluation is accomplished simply by observing the patient, certain components such as cognitive testing and review of psychotic symptoms may not fit smoothly into the rest of the interview. These are generally best covered toward the end of the interview, after the issues of greatest importance to the patient have been discussed and rapport has been established. A brief explanation that the interviewer has a few standard questions he/she needs to cover before the end of the interview serves as a bridge and minimizes the awkwardness of asking questions that may seem incongruous or pejorative.

In general, note-taking during an assessment interview is helpful to the interviewer and not disruptive of rapport with the patient. Notes should be limited to brief recording of factual material, such as dates, durations, symptom lists, important events, and past treatments, which might be difficult to keep in memory accurately. The interviewer must take care not to become so involved in taking notes as to lose touch with the patient. It is especially important to maintain a posture of attentive listening when the patient is talking about emotionally intense or meaningful issues. When done with interpersonal sensitivity, note-taking during an assessment interview may actually enhance rapport by communicating that what the patient says is important and worth remembering. This is to be distinguished from note-taking during psychotherapy sessions, which is more likely to diminish the therapist's ability to listen and respond flexibly.

In the third or closing phase of the interview, the interviewer shares his/her conclusions with the patient, makes treatment recommendations, and elicits reactions. In situations where the assessment runs longer than one session, the interviewer may sum up what has been covered in the
Dimensions of Interviewing Techniques

Although many systems have been suggested for classifying interview techniques (Elliott et al. 1987), it is convenient to think about four major dimensions of interviewing style: degree of directiveness, degree of emotional support, degree of fact versus feeling orientation, and degree of feedback to the patient. The interviewer must seek a balance among these dimensions to best cover the needed topics, build rapport, and arrive at a plan of treatment.

**Directiveness**

Directiveness in the interview ensures that the necessary areas of information are covered and supplies whatever cognitive support the patient needs in discussing them. Table 3-6 provides interventions that are low, moderate, and high in directiveness.

Low-directive interventions request information in the broadest, most open-ended way and do not go beyond the material supplied by the patient. Moderately directive interventions are narrower in focus and may extend beyond what the patient’s feeling of having gotten something from the interview. They are also the first step in initiating the treatment process because they present a provisional understanding of the problem and a plan for dealing with it. All treatment plans must be negotiated with the patient, including discussion of mutual goals, expected benefits, liabilities, limitations, and alternatives, if any. In many cases, such negotiations extend beyond the initial interview and may constitute the first phase of treatment.

### Table 3-6 Degrees of Directiveness in the Interviewer

</table>
the patient himself/herself has said. For example, confrontation makes the patient aware of paradoxes or inconsistencies in the material and requests him/her to resolve them; interpretation requests the patient to consider explanations or connections that had not previously occurred to him/her. Highly directive interventions aim to focus and restrict the patient’s content or behavior. Such interventions include yes–no or symptom-checklist-type questions and requests for the patient to modify behaviors that impede the progress of the interview.

Supportiveness

Patients vary considerably in the degree of emotional and cognitive support they need in the interview. Table 3–7 provides examples of emotionally supportive interventions. Each such intervention supports the patient’s sense of security and self-esteem. While some patients may come to the interview feeling safe and confident, others have considerable anxiety about being criticized, ridiculed, rejected, taken advantage of, or attacked (literally so in the case of some psychotic patients).

Overt manifestations of insecurity range widely, from fearful demeanor and tremulousness to requests for reassurance to haughty contumaciousness. The interview’s task is to identify such anxiety when it arises and respond in a manner that conveys empathic understanding, acceptance, and positive regard.

Obstructive interventions are one that (usually unintentionally) impede the flow of information and diminish rapport. Table 3–8 gives common examples of such interventions. Compound or vague questions are often confusing to the patient and may produce ambiguous or unclear answers. Biased or judgmental questions suggest what answer the interviewee will hear or that he/she does not approve of what the patient is saying. “Why” questions often sound critical or invite rationalizations. “How” questions better serve the purposes of the interview. (“How did you come to change jobs?” rather than “why did you change jobs?”) Other interventions are obstructive because they disregard the patient’s feeling state or what he/she is trying to say. Paradoxically, this may include premature reassurance or advice.

</table>
Fact versus Feeling Orientation

Interviews differ in the degree to which they focus on factual–objective versus feeling–meaning oriented material. Tables 3–9 and 3–10 provide examples of interventions of both types. The interviewer must determine what the salient issues are in a given case and develop the focus accordingly. For example, at one extreme, the principal task in assessing a cyclically occurring mood disorder might be to delineate precisely the symptoms, time course, and treatment response of the illness. At the other end of the spectrum might be a patient with a circumscribed difficulty in living, such as the inability to achieve an intimate, lasting love relationship. In such a case, the interviewer may focus not only on the facts of the patient’s interactions with others but also on the feelings, fantasies, and thoughts associated with such relationships.

Feedback

Interviews differ in how much the interviewer conveys to the patient of his/her own thoughts, feelings, conclusions, and recommendations. Table 3–11 presents common types of feedback from the interviewer. Judicious statements about the interviewer’s ongoing thoughts and feelings can be used to pose questions or make clarifications or interpretations while enhancing rapport and trust. Communication of factual information, formulations of the problem, and treatment recommendations are the foundations of joint treatment planning with the patient. Responding to questions and giving advice may serve an educational purpose, as well as enhancing the alliance. When responding to requests for advice or information, the interviewer must first take care to be sure of what is being asked, and for what reason.

There are little systematic data on the superiority of one clinical interviewing style over another, but what there are suggest that many styles can be used effectively. Rutter et al. have investigated this question in a series of naturalistic and experimental studies of interviews of parents in a child psychiatry clinic (Cox et al. 1981, 1988; Rutter et al. 1981). The major findings of these studies are as follows:

1. Active, structured techniques are no better than non-directive styles in eliciting positive findings (i.e., areas of pathology). However, active techniques are better in eliciting more detailed and thorough information in areas where pathology is found and are also better at delineating areas without pathology.
2. An active, fact-gathering style does not prevent the interviewer from effectively eliciting emotional reactions from informants.
3. Use of open questions, direct requests for feelings, interpretations of feelings, and expressions of sympathy are associated with greater expression of emotions by informants.
4. Less activity on the interviewer’s part is associated with more informant talkativeness and spontaneous emotional expression. Less directive techniques also tend to produce more emotional responses at times when they are not specifically requested. Conversely, more active styles of asking about feelings may be more effective for informants who are low in spontaneous emotional expression.
5. In summary, techniques that actively elicit both facts and emotions are likely to produce the richest, most detailed database. When skillfully used, these do not impair the doctor–patient relationship.

### Special Problems in Interviewing

#### The Delusional Patient

**Clinical Vignette 4**

A 26-year-old man presented to the emergency department seeking a safe haven from “the mob.” He was convinced that he was being set up to be killed, as evidenced by the sequence of license plate numbers of the cars that had passed him on the way to work. He had initially gone to a police station, which had referred him to the hospital.
Psychotic patients often present with a variety of delusions—fixed, false beliefs that are not consistent with their cultural milieu. Delusions may be persecutory, grandiose, or a variety of other types. Conducting an interview with a patient who is not in touch with reality can be unsettling: often the patient is aware that what he/she is saying is odd and may seek reassurances that he/she is believed. The interviewer must walk a fine line between giving what reassurance he/she can, while at the same time not validating the delusions. Often the question “do you believe me?” can be interpreted as “will you help me?” The clinician should not simply agree with a patient’s bizarre belief system. He or she might instead express genuine surprise at the ideas presented (a surprise which the patient likely shares, thus enhancing a sense of common purpose) and question if the patient is sure of this or how does he/she know for certain. If pressed, a reasonable response could be “it seems unlikely,” with an offer to work with the patient to discover the truth. It may also be helpful to agree with the affect but not with the facts. Thus, one might say, “You don’t feel safe out there right now.”

Agitation is a sign of many different types of mental disorders as well as a part of normal temperament variation. Extreme degrees, leading to violence, are a common reason for psychiatric as well as legal interventions. The clinical interview requires, first of all, that a safe environment be established. No helpful intervention can be made in an atmosphere of fear and uncertainty. Adequate resources such as additional people, physical restraint, seclusion, or distance must be used in order to obtain an appropriate assessment (Marder 2006).

In conducting an interview with an unpredictable or potentially violent person, it is appropriate to make the patient aware of one’s concern that he/she might be unable to control himself/herself and find out if the patient agrees. If he/she does, then the patient and interviewer together must ensure a safe environment. Most potentially, violent people fear the violence as much as anyone and are relieved by efforts to help them maintain control—even with the use of four-point leather restraints (though this must always be the last resort, used only when all else fails).
Clinical Vignette 7

If a patient is unable to agree with needed measures, and the potential for violence mandates their use, the intervention should proceed in an orderly manner. Explanation should be given to the patient concurrently, including exactly what will be done, the reason for it, assurance of the patient’s safety, and what behavioral requirements there are for the cessation of the intervention.

Sometimes patients will refuse to conduct an interview after safety measures have been instituted. They will insist that the interview-room door not be left open, that security personnel leave, that they be permitted out of a seclusion room, or that restraints be removed. Assuming that the initial decision for such intervention was appropriate, it is useful to remind the patient that a valid assessment is the quickest way to achieve what he/she wishes. No one should accept an unsafe situation as part of a bargain to get questions answered.

The Hostile Patient

Clinical Vignette 6

A 15-year-old girl is brought to the office by her mother because of illicit drugs found in her room. The patient slouches in a chair and tells the interviewer, “I don’t like you and I don’t like this place. My mother’s the one with the problem, talk to her.”

A therapeutic alliance is the sine qua non of most interviews. Without an agreed basis on which to work, anything an interviewer says can be interpreted as intrusive and provoke an angry response. Overt hostility must be acknowledged right at the outset, or the patient may perceive further things to feel hostile about. Pointing out the incongruity of the anger, once it is acknowledged, can be the next step; after all, the clinician presumably is conducting an evaluation in the service of the patient.

An understanding of the true object of the patient’s anger, such as her mother in the case above (or more precisely, what the mother represents), can be helpful, especially if the clinician can define a boundary between this object and himself/herself: “I’d like to be of help to you; your mother will have to wait.”

Clearly, responding to hostile provocation with hostility has no place in an interview. Ignoring it, or being too accommodating to provocative acts, can have deleterious effects as well, by breaking the usual interview frame of two people working together to solve the problems of one of them.

The Depressed Patient

Clinical Vignette 7

A 70-year-old man is brought for evaluation by his children. Since his wife’s death 8 months ago, he has lost 30 pounds. The children report that he leaves his home only when they strongly encourage him, and that he has stopped joining in conversation.

Talking to a profoundly depressed patient can sap the energy of the interviewer. The patient will often have the classic symptom of prolonged latency of response; it can be difficult to avoid repeating the question, suggesting responses, or simply changing the line of inquiry. An occasional rephrasing or seeking to find out if the patient understands the question is all the interviewer can do. A great deal of patience is required when conducting an evaluation of someone very depressed.

Another difficult aspect of dealing with a very depressed person is the emotional drain. The pessimism, hopelessness, and helplessness of these patients can be somewhat infectious. Those who express existential despair (lamenting the human condition) or who have suffered a painful loss that the interviewer might tend to identify with (e.g., the death of a child) can evoke an empathic response of shared pain or futility. It is important to recognize this as another element of the diagnosis and reflect a bit of it back to the patient to aid in rapport-building but keep oneself well centered.

Crying is a frequently encountered affect in the interview of a depressed patient, which is sometimes problematic. Especially when the patient’s first priority is expressing the depth of his emotion, it may be difficult to get needed information. At times, the patient must be told of this difficulty and the importance of completing the assessment in a timely manner in order to reduce his/her pain.

When the widower insists that life is meaningless now that he is old and alone, the interviewer must be careful to detect the nihilism of depression and to educate the patient about this process.

The Confused Patient

Clinical Vignette 8

A 76-year-old woman is brought by her family for evaluation after she was found wandering in the streets surrounding her home. She has had a progressive decline in her memory and ability to care for herself, and her family is concerned that she might need to be placed in a nursing home. The patient has become combative at times when caretakers are brought into the home to assist her, because she believes they are trying to rob her.

Assessing a patient with cognitive loss requires a ratcheting down of expectations for historical data and the realization that the going will be slow. Most patients who are confused will not be able to respond to open-ended questions reliably; the unstructured stimulus requires too much secondary processing on the patient’s part. Instead, simple yes–no questions, of no more than about 10 words, are likely to yield the most reliable responses.

Patients with memory problems will also need to be frequently reoriented to their surroundings as well as to the task at hand. It is helpful to query the patient about his/her current situation at times and provide the reassurance of his being in a treatment situation dedicated to his/her welfare.

The mental health status exam of the confused patient deserves special attention. It is important that the patient’s performance be characterized precisely: both the requested task and the patient’s response should be included. The format of most standard tests—serial 7s, remembering three objects, presidents backward, digit span, spelling world backward—does not require explication; it is important, though, to describe exactly how the patient responded to which test rather than just a notation of poor memory or concentration.
With confused patients, more than any other, the setting of the interview can markedly affect the results. Patients with impaired cognitive processing are very susceptible to extraneous distractions—the capacity to focus attention is often lost. As much as possible, stimuli other than the interviewer should be at a minimum. When outside forces interfere, they should be noted as part of the database; this includes physical aspects of patient comfort, such as uncomfortable positioning in restraints or pain from underlying medical illness.

**Clinical Vignette 9**

A woman in her 30s is referred by another patient for an evaluation for anxiety and work inhibition. She describes a series of unhappy relationships and then begins to discuss what she knows of the interviewer’s personal life, by way of comparison. She announces, “Jill was right—you are very easy to talk to. What am I going to do when I fall in love with you? I guess that’s easy—the real question is, what are you going to do?”

Psychiatric assessment requires that the interviewer display a degree of emotional openness and support that can stimulate a powerful longing in some patients. Few aphrodisiacs can compare in potency to the sincere, nonjudgmental interest from another person, especially one in a position of relative power. In particular, patients who have been sexually abused as children, or those who have been unable to achieve close relationships, will sometimes find the interview an invitation to greater intimacy.

At one level, the management of this problem is straightforward. The patient is reminded of the limits of the situation, what role he/she and the interviewer have, and the inviolable boundaries that apply. However, it is important to set limits in a way that does not imply reproach. A good clinician will try to foster an atmosphere wherein the patient can feel comfortable sharing anything, including such deeply personal things as sexual attraction. Therefore, the interviewer must maintain the boundary between expression of sexual feelings and acting on them.

The interviewer’s own emotional reaction to the patient, including at times sexual attraction (or repulsion), can play a part in how he/she responds to seductiveness. An awareness that the patient is usually responding more to what he/she needs to see or hear (i.e., to transferential perceptions), rather than to the actual person of the interviewer, can help keep the interaction in perspective.

Seductiveness on an initial interview, such as described above, is rare. It may signify a frontal lobe dysfunction or hypomania, or a misunderstanding of the clinical situation. Pointing out this misunderstanding is an effective way of management. “My understanding is that you’re here for help with some things that are troubling you. Helping as your therapist is something I can do, but that is a specifically limited relationship.”

**Cultural Disparity**

Significant cultural, religious, ethnic, racial, language, and other differences between the patient and the interviewer create at least three major problems, which are closely related: the basic problem of obtaining information, the interpretation of information in the appropriate cultural context, and finally the establishment of necessary rapport. The information-gathering problem is obvious when the patient literally speaks a different language, but it can be just as problematic, or even more so, when the patient belongs to a subculture with idiosyncratic word usage, nuances, values, and styles of interaction.

The use of an interpreter deserves special mention. Whenever possible, an unbiased third party should be used rather than a family member. The interpreter must be explicitly instructed to interpret verbatim, as much as possible, except perhaps in the fortuitous circumstances where the interpreter is also a clinician. The purpose of the interview, how long it will last, and of course the need to respect confidentiality should all be explained. Confidentiality is especially important when dealing with members of small minority groups, because the likelihood of common business or social ties is high.

Membership in subcultures creates problems for understanding “peculiarities” of word choice and concept. Assessment for delusional beliefs in particular must take the patient’s background into account; a delusion cannot be diagnosed if the belief is shared by a significant percentage of the patient’s peers. The degree of emotional expressiveness, guardedness in the presence of others, the amount of eye contact, the rate and tone of speech are all cultural variables. Consultation with other members of the culture will help to set the norm against which the patient must be evaluated.

The final issue, and the one described in the last example, is the degree of comfort a patient can have with an “outsider.” The wish to be understood, to be accepted, and to be valued are part of the human condition and are at work in nearly every interview. When there are cultural discrepancies between the patient and the clinician, fears of being misunderstood can be overwhelming. It is the interviewer’s responsibility to reassure the patient of his/her commitment to understanding the patient as best as possible and to take what steps he/she can to minimize the chance of distortion.

**Clinical Vignette 10**

A man in his 20s is brought to the emergency room by his male lover/partner for treatment of self-inflicted wrist cuts. These had occurred during a violent fight between the two. The patient refused to be evaluated by a male psychiatric resident unless he first answered a long list of questions about his attitudes toward gays.

A man in his 50s presents to a hospital emergency room complaining of memory loss after having fallen down. A work up for mental status change is begun, until the patient is recognized by a resident who had seen him while moonlighting in another hospital. His complaint of memory loss had mysteriously vanished after spending the night and eating breakfast in the emergency room.

**Clinical Vignette 11**

A man in his 50s is brought to the emergency room by his male lover/partner for treatment of self-inflicted wrist cuts. These had occurred during a violent fight between the two. The patient refused to be evaluated by a male psychiatric resident unless he first answered a long list of questions about his attitudes toward gays.
One of the basic expectations of the doctor–patient relationship is honesty. Patients come in asking for help and are expected to give whatever information is required honestly. One of the formative events of any clinician’s professional development is the dawn of awareness that sometimes patients lie, either by omitting important parts of the history or by actually fabricating symptoms. There are many different reasons for the deception. Most commonly, the patient has a different agenda, which he/she feels must be kept hidden from the interviewer and which is often directed toward achieving the secondary gains of illness. At times, the patient hides symptoms because of his/her own fear of them or because of his/her fear of what treatment might be required. A patient who is mistrustful of the medical establishment may be unwilling to share important information, believing that the patient himself/herself is the best judge of what care he/she needs, and will couch the patient’s replies in the way he/she thinks will best achieve his/her own ends. In addition to consciously lying to achieve secondary gain (known as malingering), there is another scenario in which patients speak falsely. Factitious disorder, or Munchausen’s syndrome, is an example of a patient making false statements about himself/herself and his/her disease. These are usually elaborate tales of illness, often accompanied by hidden actions to bolster the story or even to induce sometimes life-threatening symptoms. In this circumstance, there is no secondary gain; the motivation appears to be simply to gain the patient role and all the benefits that entail, and fool medical caregivers in order to satisfy deeper psychological needs. Both of these types of deceit, malingering and factitious, must be distinguished from situations in which the patient is unaware that he/she is giving misinformation. Patients with conversion disorder experience neurological symptoms purely on a psychological basis and may be unable to speak, walk, or see with no organic defect. These patients are not being deceitful; they truly cannot function and will not until their illness is treated.

Telepsychiatry

Modern audiovisual telecommunication offers the possibility of bringing psychiatric services to patients who otherwise would have no access to them. Advantages of telepsychiatry over telephonic communication are the enhanced “social presence” provided by the visual modality and the chance to observe nonverbal forms of communication. At the same time, the procedure still has technical limitations that may degrade the visual image and contribute to a depersonalized quality in the interview. Research has shown that, in terms of quantity of usable visual cues and patient satisfaction, telepsychiatry interviews are better than those conducted over the telephone, but not as good as in-person interviews (Ball et al. 1995, Gammon et al. 1998).

Experience in telepsychiatry suggests the following guidelines to enhance the effectiveness of the interview (Hilty et al. 2002):

1. The interviewer should practice with staff before attempting a telepsychiatry interview with a patient.
2. The interviewer must pay extra attention to his/her own and the patient’s nonverbal communication. In the present case, attention to facial expression, body posture, and body mobility would be especially important.
3. The setup should provide for end camera control, so that the interviewer can refocus or zoom the camera as needed.
4. The interviewer should learn to avoid rapid movements, which will transmit with poor quality.
5. The equipment should use as high a bandwidth Internet connection as possible (preferably, at least 384K) to maximize clarity and avoid movement artifacts (Yoshino et al. 2001).

Valiant GE (1977) Adaptation to Life. Little Brown, Boston, MA, USA.
Introduction: The Cultural Matrix of Psychiatry

Although it has long been recognized that the mode of expressing psychological distress and behavioral disturbances varies with cultural beliefs and practices, a growing body of evidence shows that the effects of culture are more far-reaching. Research has clearly demonstrated that the causes, course, and outcome of major psychiatric disorders are influenced by cultural factors (Kleinman 1988, Kirmayer 2001, Leff 2001, López and Guarnaccia 2000). For example, international studies by the World Health Organization have provided compelling evidence that the prognosis for schizophrenia is better in some developing countries than it is in England or the US (Jablensky et al. 1994, Craig et al. 1997). Wide variations in the prevalence of many psychiatric disorders across geographic regions and ethnocultural groups have been documented with current standardized epidemiological survey methods (Canino et al. 1997, Kirmayer and Groleau 2001). In addition, social and cultural factors are major determinants of the use of health care services and alternative sources of help (Rogler and Cortes 1993).

For all these reasons, a careful assessment of the cultural context of psychiatric problems must form a central part of any clinical evaluation (GAP 2002). Beyond this, culturally based attitudes and assumptions govern the perspectives that both patient and clinician bring to the clinical encounter. Lack of awareness of important differences can undermine the development of a therapeutic alliance, and the negotiation and delivery of effective treatment.

The changing demography of North America has made the recognition and response to cultural diversity increasingly important in psychiatric practice (GAP 2002, Gaw 1993, Lim 2006). The US and Canada have always been the countries of immigrants, but earlier waves of migration involved people from European backgrounds who shared many commonalities. In the US, the overarching ideology took for granted that these newcomers would gradually become just like all other Americans through a process of cultural assimilation (Portes and Rumbaut 1996, Susser and Patterson 2001). However, sociological research has shown a high degree of retention of ethnic culture with the persistence of religious practices, family life cycle rituals, and ethnic enclaves in many cities. Added to this is the recognition of the importance of maintaining and renewing ethnocultural identity to combat the legacy of racial discrimination against African Americans, Native American people, and other groups. This has led to rethinking of the notion of assimilation to take into account other modes of acculturation including the development of multiple cultural identities.

More recent waves of global migration from south to north and east to west have brought together new mixes of people with greater differences in their cultural assumptions with corresponding challenges for intercultural clinical work. Although the US maintains a dominant social ethos and “mainstream” culture, the country is moving rapidly toward a composition of a majority of minorities. This is also reflected in the changing demography of the profession of psychiatry itself.

These changes, along with larger forces of globalization, have encouraged a fresh look at culture in every area of psychiatry. In clinical practice, “cultural competence” has become the rubric under which to advance a broad range of skills and perspectives pertinent to working with a culturally diverse clinical population (GAP 2002). In the sections that follow, we will summarize some of the concepts and approaches that can inform the culturally competent clinical practice.

What is Culture?

There is a famous saying to the effect that “we don’t know who discovered water but it wasn’t the fish.” So it is with
culture: we are immersed in our own cultural worlds from birth, and consequently, our culture is largely implicit and unexamined. Just as we are unconscious of many of our own motivations and patterns of thought and behavior until they are reflected back to us by others, so too we are unconscious of our cultural background knowledge and assumptions. Bringing the cultural unconscious to light may be more difficult than facing the individual unconscious because institutions and others around us may reinforce our assumptions and resist any attempt to question them. Our explicit appreciation of culture usually comes from intercultural encounters, which make us suddenly aware of culture through difference. More formally, anthropological research comparing different cultures allows us to see the tacit assumptions of our own worldviews. There is no substitute for this sort of systematic reflection on cultural difference, which should extend to the critical analysis of the construction of psychiatric knowledge (Lock and Gordon 1988, Young 1995).

Older views of culture were based on ethnographic studies of relatively isolated, small-scale societies. Many accounts tended to assume that cultures were finely balanced systems and that, as a result, everything was for a purpose and had an adaptive function for the group (if not always for the individual). The outsider was thus cautioned not to pass judgment on cultural differences or to see pathology where there was a simple difference. This is still a wiser advice. However, it is clear that cultures are not homeostatic systems in a steady state or equilibrium but are constantly shifting and evolving systems. They may be driven by conflict and create maladaptive circumstances, not only for disadvantaged individuals, but for specific groups or even the whole society. Thus, while refraining from prejudging specific cultural values or practices, the clinician must nevertheless consider that every culture encompasses practices that may help or hinder patients, and aggravate or ameliorate any given type of psychopathology. Each society tends to cultivate blind spots around the specific forms of social suffering that it produces (Kleinman et al. 1997). Openness, respect, and capacity for collective self-criticism are thus key elements of any transcultural clinical encounter.

At the same time, anthropologists have come to recognize the high level of individual variability within even small cultural groups, and the active ways in which individuals and groups make use of a variety of forms of knowledge to fashion an identity and a viable way of living. In urban settings where many cultures meet, individuals have a wide range of options available, and can position themselves both within and against any given ethnocultural identity or way of life. This has led the anthropologists to rethink the notion of culture or even to suggest that it has outlived its usefulness.

Indeed, the modern world includes forms of electronic communication and rapid transportation that have begun to weave the whole globe together in new ways. This results in the intermixing of cultural worlds and the creation of new ethnocultural groups and individuals with multiple or hybrid identities. Many people now see themselves as transnational, with networks of affiliation and support that span great distances. The mental health implications of these new forms of identity and community have been little explored, and will be an increasingly important issue for psychiatry in the years to come (Bibeau 1997, Kirmayer and Minas 2000).

As this brief discussion makes clear, the notion of culture covers a broad territory. It is useful precisely because of this breadth, but to apply it to clinical practice we need to make some further specifications and distinctions. In the North American context, it is useful to distinguish notions of race, ethnicity, and social class from culture.

Race is a term used to mark off groups within and between societies. Racial distinctions generally reflect a few superficial physical characteristics and hence have little correlation with clinically relevant genetic variation. The boundaries of any racial group are socially defined and have no biological reality (Graves 2001). Race is usually ascribed by others and cannot be readily changed or discarded unless larger social criteria change. Race is significant as a social category that is employed in racist and discriminatory practices. Racism is clinically important because of its demonstrable effects on mental and physical health, individual and collective self-esteem, and health service utilization (Hollar 2001, Smedley, Sith and Nelson 2003). The painful history of slavery and racial discrimination in the American society makes it difficult for people to talk readily about their experiences of racism, and so the clinician needs to work at becoming clear, sensitive, and open to discussing the impact of racism on patients’ lives, as well as its inevitable expressions in his or her own thinking (Pinderhughes 1989).

Ethnicity refers to the collective identity of a group based on common heritage, which may include language, religion, geographic origin, and specific cultural practices. Ethnic identity is often constructed vis-à-vis others and a dominant society. Hence, it is sometimes assumed that “foreigners” or minorities have ethnicity while the dominant group (e.g., Americans of British or Northern European extraction) does not. This obscures the fact that everyone may become aware of an ethnic identity in the right context (in China, an American clearly has a distinct ethnicity). Ethnicity may be chosen or ascribed by others. For example, the US census defined five ethnoracial blocs: White, African American, Hispanic, Asian American and Pacific Islander, and American Indian and Alaska Native. These are heterogeneous categories variously based on race, language, geographic origin, and ethnicity. Although the categories are fictive, they have acquired practical and political reality because they have been used to present epidemiological findings and define health-service needs (Hollinger 1995). Nevertheless, the clinician must recognize that to meet the patient on a common ground requires a much more fine-grained notion of ethnocultural identity than afforded by these crude categories.

Finally, social class reflects the fact that most societies are economically stratified and individuals’ opportunities, mobility, lifestyle, and response to illness are heavily constrained by their economic position. Issues of poverty, unemployment, powerlessness, and marginalization may overshadow cultural factors as causes of illness and influences on identity and help-seeking behavior. Violence is a particularly striking example in North American society of the overlap of exclusion, poverty, discrimination, and intergenerational transmission of trauma.

The notion of culture is sometimes extended to speak of various subcultures or the cultures of professions. In this sense, we can speak of the cultures of biomedicine and of
psychiatry. Each of these systems of knowledge includes a wide range of behavioral norms and institutional practices that may be familiar to clinicians but novel and confusing to patients. However, familiar cultural notions of self and personhood underwrite these technical domains, which therefore serve to reinforce larger cultural ideologies (Lock and Gordon 1988). This becomes clear when we consider alternative systems of medicine such as traditional Chinese medicine or Indian Ayurveda, which are based on different notions of the person (ethnopsychology), the body (ethnophysiology), different roles for patient and healer, and, indeed, different epistemologies (Leslie and Young 1992). Even the understanding and practice of biomedicine may differ across countries; so the clinician should not assume that familiar terms always refer to the same practice.

**Culture and Gender**

Gender refers to the ways in which cultures differentiate and define roles based on biological sex or reproductive functions. Because of this link with physical aspects of sex, there is a tendency to view gender differences as biologically given. However, while some distinctions may be closely related to the physiological differences between males and females, most are assigned to the sexes on the basis of specific cultural beliefs and social organization (Comas-Diaz and Greene 1994).

Men and women do have some fundamentally different experiences of their bodies, of their social worlds, and of the life course. It has been suggested that women are more in touch with their bodies because of the experiences of menstruation, childbearing, childbirth, breast-feeding, and menopause. These differences may be as substantial as any between disparate cultures. At the same time, there is much evidence that these bodily grounded experiences vary substantially across cultures. For example, anthropologist Margaret Lock (1993) has shown that Japanese women report fewer bodily symptoms of menopause and do not think of the end of menstruation as a distinctive “change of life” in the same terms as many women in North America.

There are also important gender differences in styles of emotional expression, symptom experience, and help-seeking. In epidemiological surveys in the US, women tend to report more somatic symptoms as well as more emotional distress, and they are more likely to seek help for psychological or interpersonal problems. However, the gender difference in symptom reporting varies significantly cross-nationally (Piccinelli and Simon 1997).

In North America, important differences have been documented in male and female styles of conversation that are relevant to the clinical context (Tannen 1994). In general, women tend to give more frequent acknowledgments that they are listening to a speaker. They may give signs of assent simply to indicate that they are following the conversation. Men tend to be more taciturn and, if they signal assent, it usually means that they actually agree with the speaker. These differences in communication style may lead to systematic misunderstandings between men and women that are further aggravated by cultural differences in gender roles and etiquette. This may occur in clinical settings where rules for gender appropriate behavior and interaction between men and women may be misinterpreted as evidence of individual personality traits or psychopathology (as illustrated in the Clinical Vignette 1).

---

**Clinical Vignette 1**

When an ultraorthodox Jewish family arrives for their consultation, the female psychiatrist, who is dressed in a short skirt, welcomes them offering her hand to the father in greeting. He is confused and offended, avoids eye contact, and is reluctant to proceed with the session. The female doctor’s style of dress and friendly handshake were viewed as disrespectful or as indicating her lack of familiarity with norms of conduct with observant orthodox families.

In many societies, gender is associated with marked differences in power and social status. For example, in patriarchal societies, men have specific power and privileges that give them a measure of control over the lives of women. This is often coupled with responsibilities for maintaining family honor and well-being. In recent years, the North American society has espoused social and political equality in gender roles. From this egalitarian point of view, patriarchal families may seem oppressive to women. However, women may accept and participate in cultural definitions of their roles that appear restrictive by North American cultural norms but make family life meaningful. Any judgment as to whether a given family’s relationships are oppressive or pathological must not only take into account social norms and practices but also explore the meaning of issues and events for the individuals involved. A common dilemma in assessment occurs in clinical interviews when women show culturally prescribed deference in the presence of their husbands or male kinfolk. (Clinical Vignette 2).

**Clinical Vignette 2**

A 29-year-old East Indian woman, in the US for six months, presents with symptoms of depression and posttraumatic stress disorder (PTSD). Throughout the initial evaluation, the patient looks away from the male psychiatrist, never making an eye contact. The interviewer is concerned that he may have offended the woman in some way. The female interpreter explains that the patient is showing respect by not looking directly at a male in authority.

Differences in cultural definitions of gender roles may become sources of conflict after migration. Culturally prescribed patterns of marriage and child bearing may be central to the social status, identity, and self-esteem of men and women even when they are not given the same importance in the dominant culture. For example, for women

**Clinical Vignette 3**

A 28-year-old woman from South Asia has an arranged marriage with an older man from the same religious community, who has lived all his life in the US. The couple has been unable to conceive for five years and is in the midst of extensive infertility treatments. The husband complains that she is paranoid and does not want to work or go out of the house. The woman tearfully relates that she feels depressed and ashamed because of her predicament, and fears that her marriage will end if she cannot bear children.
from some backgrounds, a socially valued identity may be strongly linked to childbearing and infertility may precipitate a crisis both for the individual and the extended family. As seen in Clinical Vignette 3, this may express itself not only in symptoms of demoralization and depression but in intense concern about one’s social standing with others in the community.

The Cultural Formulation

In an effort to address the cultural dimensions of clinical assessment, DSM-IV-TR introduced an outline for a cultural formulation (Table 4–1). This outline covers the major areas that a clinician should explore in a comprehensive evaluation. These are integrated in a formulation that helps to account for symptomatology, diagnosis, prognosis, and appropriate treatment (Lewis-Fernandez and Diaz 2002). The cultural formulation may go well beyond the DSM-IV-TR categories to consider many sorts of problems and predicaments relevant to the patient’s well-being.

Table 4–1 DSM-IV-TR Outline for the Cultural Formulation

- Identity of the individual
- Explanations of the illness
- Psychosocial environment and levels of functioning
- Relationship between the individual and the clinician
- Overall assessment with implications for diagnosis and care

The cultural formulation is merely intended as a checklist or reminder to encourage the clinician to perform the needed exploration and integration of a broad range of relevant social and cultural information. Clearly, cultural considerations may apply to every aspect of the clinical assessment and interview, and must not be used only as an afterthought to the standard psychiatric interview.

Ethnocultural Identity

The first dimension of the cultural formulation involves ethnocultural identity. This includes the individual’s ethnic or cultural reference groups and the position of these groups vis-à-vis the larger society. Certain groups have a specific ethnocultural identity ascribed to them by others; this may have an impact on individuals’ everyday experience and narratives of identity whether or not they are explicitly aware of it.

In a world of mass migration and intermingling of people over generations, identity is very often hybrid, multiple, and fluid (Bibeau 1997). For immigrant and ethnic minorities, it is important to understand the degree of involvement with both the culture of origin and the host culture. Ethnic identity may be situational and may shift with social context. The ethnocultural and religious groups with which the patient identifies the most may depend on who asks the question and in what context. For example, whether someone self-identifies as Canadian, West Indian, or Trinidadian may depend on the perceived identity of the interviewer and the setting where the interview takes place.

Language is central to identity for many people and has a profound effect on clinical encounters. Individuals who speak multiple languages, learned at different stages in their life, may have different memories, effects, and interpersonal schemas associated with the use of each language. Languages may be associated with developmentally important relationships and tied to specific areas of conflict or mastery. Personal and political allegiances within the family and community may be expressed through choice of language.

Language is the medium through which experience is articulated; hence, the assessment of higher cognitive functions, complex emotions, and experiential symptoms of pathology all depend on the clinician’s access to the patient’s language. Patient’s who are hobbled in a second language may be misjudged as less intelligent or competent than they actually are; wishing to avoid such bias, clinicians may be overly generous in their assessment and miss significant problems or pathology.

Even where patients have a moderate level of facility in the clinician’s preferred language, they may not express themselves fully in a second language so that important details are not conveyed. The use of a second language not only affects doctor–patient communication, but also influences individuals’ ability to reflect about themselves. When the patients are forced to formulate their problems in a language in which they are not proficient, they may be less creative and effective as problem solvers. When patients are able to use their own best language, their accounts of experience become much richer, more complex, and nuanced; their thinking is subtler; they can express a wider range of affections and engage in playful therapeutic exchanges.

Multilingual people sometimes report that they feel and think differently when using a second language. This is partly due to the cognitive effort of having to find words in a language in which one is not totally fluent. Since each language favors certain modes of expression and ways of thinking, bilingual speakers may report that they feel like a different person in their other language. It follows that aspects of history and experience of a patient can be less accessible in a clinical evaluation if patients are not able to express themselves in the appropriate language. Of course, use of a second language may also afford the patient some distance from intense emotions and painful memories and so assist in coping and affect regulation. Careful attention to spontaneous or strategic shifts in the use of language in a multilingual assessment can provide the clinician with important information about areas of conflicts and strengths. This often requires the use of a trained interpreter, as discussed in a later section of this chapter.

Religion is another key marker of identity. For many individuals and communities, it may structure the moral world more strongly than ethnic or national identity. The term “spirituality” has gained currency to acknowledge the fact that many individuals maintain deeply held personal beliefs about God, the meaning of life, and what happens after death without being formally affiliated with one religion or another. Religious affiliation is also a frequent source of discrimination.

Despite the ubiquity of religious and spiritual experience, it is frequently neglected during routine psychiatric evaluation. A thorough cultural formulation requires consideration of the patient’s religion and spirituality. Areas to cover include religious identity, the role of religion in the family of origin, current religious practices (attendance at services, public and private rituals), motivation for religious
Illness Explanations and Help-Seeking

The second major dimension of the cultural formulation concerns the cultural explanations of symptoms and illness. Cultures provide systems of diagnosis and treatment of illness and affliction that may influence patients’ experience of illness and help-seeking behavior. People label and interpret their distress based on these systems of knowledge, which they share with others around them. Much research in medical anthropology has developed the idea of explanatory models, which may include accounts of causality, mechanism or process, outcome, expected course, and consequences. Not all of this knowledge is related directly to personal experience—much of it resides in cultural knowledge and practices carried on by others. Hence, understanding the cultural meanings of symptoms and behavior may require interviews with other people in the patient’s family, entourage, or community. (Kirmayer, et al. 2004, Philips, et al. 2002)

Table 4–2 provides questions for eliciting patients’ explanatory models. These questions should be modified based on the patient’s responses. For example, the origins of problems may be located not in the body but in the workings of the mind, the family, the community, the realms of ancestors or spirits, or in mythological accounts which explain the social and moral order.

In many cases, particularly with acute illness, patients may not have well-developed explanatory models. Instead, they reason by analogy on the basis of past experiences of their own or other prominent prototypes encountered in family, friends, or mass media. Once an explanatory model is evoked in conversation, patients may give formulaic accounts that accord with that cultural model or script. Therefore, to obtain more complete information about the cognitive and social factors that are actually influencing the patients’ illness experience and behavior, it is useful to begin with an open-ended interview that simply aims to reconstruct the events surrounding the symptoms and the patient’s illness experience (Groleau and Kirmayer 2004). This will reveal idiosyncratic temporal patterns of contiguity and association that may not fit any explicit cultural model. Following this, the clinician can ask about prototypes (Have you ever had anything like this before? Has anyone you know ever had anything like this before?). This will uncover salient models of illness that may shape illness experience and be used to reason analogically about the current episode. Finally, it is important to inquire into explicit cultural models using the sorts of questions devised for the explanatory model interview.

The ethnomedical systems described in anthropological texts are often idealized and complex portraits pieced together by working with cultural experts. In clinical practice, patients usually have only partial or fragmentary knowledge of the traditional explanations and treatment for their problem. Depending on the knowledge and attitudes of family and kin, and on the availability of practitioners of traditional medical systems, patients may be influenced by larger cultural systems to which they themselves do not fully subscribe. Eliciting these illness interpretations may require a high level of trust and rapport, particularly when they are viewed negatively (e.g., as “backward” or “superstitious”) or have led to conflicts with other professionals in the health care system. In many cases, people employ multiple interpretive systems that link their symptoms to salient life events and issues. This is particularly the case with serious, chronic, or disabling conditions that often receive explanation in moral, spiritual, or religious terms, as seen in Clinical Vignette 4.

In everyday life, people use culturally prescribed idioms to discuss their problems. These cultural idioms of distress cut across specific diagnostic categories. They may be used to talk about ordinary problems as well as to shape the expression of distress associated with major psychiatric disorders. For example, many cultures have notions of “nerves” (in Spanish, nervios), which signal emotional distress that may range from being mildly upset with life events to disabling anxiety or psychosis. Appendix I of DSM-IV-TR provides a list of some common idioms of distress. The same appendix also lists some well-described culture-bound syndromes, culturally distinctive clusters of symptoms that may be of pathological significance. Many culture-specific terms, however, do not refer to syndromes or idioms of distress but are actually symptoms or illness attributions that reference folk models of causality (Groleau and Kirmayer 2004). For example, susto, a term used in Central and South America, attributes a wide range of bodily symptoms and diseases (including infectious diseases and congenital malformations) to the damaging effects of sudden fright.

Clinical Vignette 4

A family from Nigeria consults for developmental delay in their 4-year-old son. Problems had become evident when they attempted to integrate the child into a preschool program. The child presents a classical profile of pervasive developmental disorder. The parents remark that their family doctor raised the possibility of autism but that they did not consider what he described applied to their son. They explain that the migration process, when the child was 2 years old, had hindered his acquisition of speech and social activities. After a few sessions it becomes apparent that the child’s difficulties had already been recognized in Nigeria but were attributed by both the maternal and the paternal lineage to sorcery on the other side of the family because they were in conflict.
Many cultural idioms of distress use bodily metaphors for experience. In seeking medical help, patients usually try to present the sort of problems they believe the clinician is competent to treat. Consequently, in biomedical settings patients tend to emphasize physical symptoms. This pattern of clinical presentation combined with the wide currency of somatic idioms of distress has led to a characterization of many ethnocultural groups as prone to somatize their distress (Kirmayer 2001). The social stigma commonly associated with psychiatric symptoms and disorders, as well as with substance abuse, antisocial behavior, and various other behaviors, may also prevent patients from acknowledging such problems and events. However, with clear communication and a respectful stance, the clinician may be able to build sufficient trust over time for patients to disclose shameful or potentially stigmatizing information.

Similarly, people commonly use multiple remedies or consult various healers for their symptoms, and may be reluctant to disclose treatments that they think the clinician will not understand or accept. They may also omit mention of preparations they view as “natural” or as foods and, hence, not included under the rubric of medications or drugs. Commonly used remedies like ginseng, St. John’s Wort, and gingko biloba have significant effects on pharmacokinetics and drug metabolism and are, therefore, important for their potential impact on physiology as well as their role in patients’ belief systems and a sense of control over their illness. A nonjudgmental inquiry by the clinician will enable patients to more freely discuss their use of traditional and alternative treatments.

**Psychosocial Environment and Levels of Functioning**

Cultural factors have a dual influence on the psychosocial environment: They determine life circumstances and, at the same time, provide interpretations of their meaning and significance for the individual. This dual effect of culture means that the clinician must explore both events and their personal and cultural meanings to understand the impact of the social environment.

There are wide cultural variations in the composition and functioning of families including the variety of people living together in a household (not always identical to the family or kin); person who is considered close or distant kin; hierarchy, power structure, and economic arrangements; age and gender roles; organization of household activities and routines; styles of expression of emotion and distress; body practices (arrangements and procedures for sleeping, eating, washing, dressing, recreation, and use of physical remedies for ailments); conflict management strategies; and the relationship of family to larger social networks and communities.

Social support must be assessed with attention to cultural configurations of the family and community. Extended multigenerational families, tightly knit religious and ethnic-cultural communities, and transnational networks, all may provide specific forms of instrumental and emotional support. Often these supports are inextricably intertwined with interpersonal obligations and demands that may constitute burdens for the individual. This complex relationship of burden and support may have crucial implications for clinical interventions. In some cases, these burdens or conflicts within the family may constitute crucial clinical problems in their own right as seen in Clinical Vignette 5.

Similarly, levels of functioning and disability must be assessed against culturally determined notions of social roles and values. It is important to recognize that the clinician’s priority may not be the most important issue for patients or their families.

In addition to these general cultural considerations, certain social situations present specific stressors with which the clinician must become familiar. All immigrants and refugees have arrived in the host country after a migration experience. For some, migration is a personal choice taken in the hopes of bettering personal and family prospects; for others, the experience is borne out of extreme difficulty and is only taken under threat of harm or death. Many new arrivals face bleak job prospects, are isolated from family and cultural institutions, and have an uphill battle as they adapt to a new language and unfamiliar social rules and obligations. Furthermore, the path that some immigrants take prior to arriving at their final destination is often lengthy, circuitous, and costly, in addition to being dangerous. It is crucial, therefore, to take into account the migration experience when evaluating immigrants and refugees. Questions must be carefully phrased and asked in a judicious manner, as not all patients will be ready to discuss their reasons for leaving their homeland. Important points to cover include the premigration lifestyle of the patient, the context of migration, the experience of migration, the postmigration experience, and the “aftermath” of migration, or the long-term adjustment and acculturation to the host society (Beiser 1999).

The stress experienced by refugees may include the confusion and disorientation of unplanned flight and exile; loss of social status, wealth, security, and community; and worry about the safety of family left behind and still in peril. Refugee claimants or asylum-seekers usually face a stressful period of uncertainty while waiting to have their status determined. The refugee-review process itself may be traumatic because it often occurs in an adversarial atmosphere that questions the veracity of the refugee’s story even as it foregrounds traumatic memory (Silove et al. 2000). Individuals who have endured war-related trauma, torture, or other forms of organized violence have special needs to insure the safety of the clinical setting and relationship (Silove 1999). In some instances, they may experience routine hospital or clinical procedures as threatening and this can undermine the clinical encounter and aggravate their condition (Clinical Vignette 6).
The growing number of undocumented people in North America also presents ethical and pragmatic challenges to the medical profession. These illegal immigrants and families may have particular mental health needs, which are largely unrecognized because there is almost no funded research or services to address them.

Clinician–Patient Relationship

The roles of healer, helper, and physician differ across cultural contexts, and patients may have correspondingly different expectations of their relationship with clinicians, including the duration, level of disclosure (Savin and Martinez 2006), formality, and emphasis on technical competence. These expectations often need to be explored, with opportunities for patients and clinicians to negotiate or explain the limitations of the roles they are able and willing to adopt. Once these differing perspectives are made explicit, a culturally appropriate and professionally acceptable relationship and working alliance can be negotiated.

Clinicians must become aware of their own ethnocultural background and identity, and reflect on how it is perceived by patients from their own and different backgrounds. The terms “cultural transference” and “cultural counter transference” have been used to acknowledge that both patient and clinician may have fantasies and responses to the other that are based on earlier relationships with others from that culture or on culturally rooted associations to the other, rather than to strictly personal characteristics (Adams 1996, Comas-Diaz and Jacobsen 1991). The history of racism, colonialism, and discrimination in a society inevitably affects the clinical encounter. As illustrated in Clinical Vignette 7, acknowledging the impact of these issues in the patient’s life may be necessary to establish trust and rapport.

Overall Assessment

The aim of cultural assessment is to integrate all of the pertinent elements of the cultural context of the patient’s identity, illness, and social context in a formulation that can guide diagnosis and treatment (Hays 2001, Tseng and Streitzer 1997). Factors associated with one aspect of the formulation may have an impact that cuts across many dimensions of illness experience and behavior. The salient aspects of culture vary across cases and may reflect issues in the dominant society as much as any intrinsic characteristics of the patient’s ethnocultural group.

For example, cultural notions of race and racism may profoundly affect every aspect of the cultural formulation (Pinderhughes 1989, Patel et al. 2000, GAP 2002). Racial categories may impose a disvalued identity on the patient; this may be resisted by reconstructing identity in a fashion that imbues one’s background with dignity and “cultural capital” (Comas-Diaz and Greene 1994, Kareem and Littlewood 1992). Race may figure in explanations of the nature of illness. For example, some native people have come to view alcoholism, diabetes, and other conditions as “white man’s illnesses,” which they suffer in large numbers precisely because of the history of colonization and racist practices. High blood pressure among African Americans has been linked to the stresses of racial prejudice and related economic and educational disparities (Dressler et al. 1998). Institutionalized racism may have a powerful impact on the level of stress and social support for individuals, families, and communities, which may fracture or unite around this issue. The legacy of racism may define the clinician–patient relationship, where it may influence the transference and undermine rapport.

Cultural Competence

Recent years have seen the development of professional standards for training and quality assurance in cultural competence (Lopez 1997, Sue 1998). This term stands for a range of approaches aimed at improving the delivery of appropriate services to a culturally diverse population. Cultural competence may involve both culture-specific and generic strategies to address a range of practical issues in intercultural work (Lim 2006, Okpaku 1998). This includes the clinician’s ability to elicit cultural information during the clinical encounter (Table 4-3), to understand how different cultural worlds of patients and their families influence the course of the illness, and to develop a treatment plan that empowers the patient by acknowledging cultural knowledge and resources while allowing appropriate psychiatric intervention. As Clinical Vignette 8 illustrates, accepting a place for culturally based interventions can facilitate psychiatric treatment.

Specific cultural competence has to do with knowledge and skills pertaining to a single cultural group, which may include history, language, etiquette, styles of child-rearing, emotional expression, and interpersonal interaction, as well as cultural explanations of illness and specific modalities of healing. Often, it is assumed that specific cultural competence
Strategies to Elicit Cultural Information

- Present an open, friendly face of the institution (have the diversity of the community represented within the diversity of the institution, with attention to not simply reproducing the class structure of the society in the institutional hierarchy).
- Make explicit the clinician’s position and identity, explain goals and methods, and use self-disclosure appropriately.
- Ask for clarification of unfamiliar terms or key terms that may be mistakenly assumed to be familiar.
- Ask for detailed description of practices related to health, illness, and coping.
- Have the patient compare situation with previous events, or experiences of others from similar backgrounds.
- Interview other family members and patient’s entourage to obtain normative framework, and identify consensus and conflicting perspectives.
- Consult knowledgeable clinicians, culture-brokers, interpreters, anthropologists, and ethnographic literature.

Clinical Vignette 8

A 16-year-old girl from Haiti presents with disorganized schizophrenia, which began around age 14. Her family has not been compliant with the treatment, and this has led to several hospitalizations of the patient in a dehydrated state. During the third hospitalization, the clinical team decide to explore the family’s interpretation of the illness. A grand-aunt insists on sending the girl to Haiti for a traditional diagnosis. The traditional healer indicates that the problem is due to an ancestor’s spirit in the mother’s family and that for this reason, it will be a prolonged illness. This explanation helps to restore cohesion in the extended family by rallying people around the patient, and her family receiving much support. The traditional interpretation and treatment has broken the family sense of shame and isolation, and promoted an alliance with the medical team and the acceptance of antipsychotic medication.

is assured when there is an ethnic match between clinician and patient (e.g., a Hispanic clinician treating a client from the same background). However, ethnic matching without explicit training in models of culture and intercultural interaction may not be sufficient to insure that clinicians become aware of their tacit cultural knowledge or biases and apply their cultural skills in a clinically effective manner.

Ethnic matching can occur at the level of the individual, the technique, the institution, or any combination of these levels (Weinfield 1999). At the level of the individual, it may be easier to establish rapport when clinician and patient share a common background. However, there is a risk that some issues may be left unexplored because they are taken for granted, or are awkward to approach. There is also difficulty when the patient’s expectations of a fellow community member are not met because the clinician applies the rules and limits dictated by professional training. This may include expectations of receiving special treatment, of being cured quickly, of becoming friends, or of intervening appropriately on behalf of other family or community members.

In many cases, however, ethnic matching is only crude or approximate. For example, the term *Hispanic* covers a broad territory with many cultural, educational, and social class differences that transcend language (Arcia et al. 2002). Indeed, there is enormous intracultural variation and no single person carries comprehensive knowledge of his own cultural background, and so there is always the need to explore local meanings with patients.

In the course of professional training, clinicians may distance themselves from their own culture of origin and become reluctant or unable to use (or understand the impact of) their tacit cultural knowledge in their clinical work. Clinicians from ethnic minority backgrounds may resent being pigeon-holed and expected to work predominately with a specific ethnicultural group. Patients may have complex reactions to meeting a clinician from the same background. These issues require attention and sensitive exploration just as much as the feelings evoked by meeting someone from a different background.

At the level of technique, the clinician familiar with a specific ethnicultural group learns to modify his or her approach to take advantage of culturally supported coping strategies. For example, religious practices, family and community supports, and appeals to specific cultural values may all provide useful strategies for symptom management and improved functioning. Traditional diagnostic and treatment methods may be used in concert with conventional psychiatric treatments. The clinician may use his or her own person differently in recognition of cultural notions of healing relationships, adopting a more authoritative stance, making selective use of self-disclosure, or participating in symbolic social exchanges with patients and their extended families to establish trust and credibility.

At the level of institutions, ethnic match is represented in the organization of the clinical service, which should reflect the composition of the community it serves (Kareem and Littlewood 1992). This is not merely a matter of hiring practices but also involves creating structures that allow a measure of community feedback and control of the service institution. When people feel a sense of ownership in an institution, they will evince a higher level of trust and utilization. It is important, therefore, for clinicians to understand how the institutional setting in which they are working is seen by specific ethnicultural communities.

Increasingly, clinicians work in settings where there is great cultural diversity that precludes reaching a high level of specific competence for any one group. Changes in migration patterns and new waves of immigrants and refugees lead to corresponding changes in patient populations. For all these reasons, it is crucial to supplement specific cultural competence with more generic competence that is based on a broad theoretical understanding of culture and ethnicity. Generic cultural competence abstracts general principles from specific examples of cultural differences. The core of generic competence resides in clinicians’ understanding of their own cultural background and assumptions, some of which are related to ethnicity and religion, and many of which are derived from professional training and the context of practice. Appreciating the wide range of cultural variation in gender roles, family structures, developmental trajectories, explanations of health and illness, and responses to adversity allows the clinician to ask appropriate questions about areas that would otherwise be taken for granted. The culturally competent clinician has a keen sense of what he or she does not know, and has a solid respect for difference.
While empathy and respectful interest allow the clinician to gradually come to know another’s world, the clinician must tolerate the ambiguity and uncertainty that comes with not knowing. In the end, patients are the experts in their own experiential worlds, and cultural context must reconstructed simultaneously from the inside out (through the patient’s experience) and from the outside in (through an appreciation of the social matrix in which the patient is embedded).

The wide range of specific and generic skills needed for competent intercultural work means that most clinicians will find it helpful to work in multidisciplinary teams that contain cultural diversity that reflects the patient population. A variety of models for such team work have been developed (Kareem and Littlewood, Kirmayer et al. 2003).

**Working with Interpreters and Culture Brokers**

A key skill, which has not been addressed in many training programs, concerns as to how to work with interpreters (Table 4–4). In the absence of familiarity with this technique and quality assurance standards insisting on appropriate use of interpreters, many clinicians simply try to avoid the situation, relying on patients’ sometimes-limited command of the clinician’s language. This is unfortunate, and may lead to errors in diagnosis and management as well as the failure to engage and help many patients (Karliner et al. 2007).

There are several models of working with interpreters (Westermeyer 1989). Medical interpreters have adopted a code of ethics and model of working that owes much to forensic and political interpreting. Their goal is to provide accurate, complete, and literal translation of the statements of patient and physician. This model tends to portray the interpreter as providing a transparent window or conduit of communication between clinician and patient. In this approach, the clinician addresses the patient directly as though the interpreter is not present. The interpreter may speak in first person for the patient and for the clinician alternately. The model assumes that it is possible to achieve complete and accurate translation of messages in both directions, and treats the interpersonal triad of doctor–interpreter–patient as if it was a dyad. To do so assumes that the interpreter does not have an independent relationship with patient or clinician. Of course, this is certainly not the case in any clinical encounter that goes on for a time or involves repeated meetings. Indeed, at the level of transference, it is never the case because the mere presence of another person immediately evokes distinctive thoughts, feelings, and fantasies. Then too, the presence of the interpreter inevitably changes a dyad into a triadic social system with its own complex interpersonal dynamics. These dynamics are complicated by the ethnocultural background of the interpreter and his or her own cultural assumptions.

The very idea of literal translation is also problematic. Across languages, the words and phrases with similar denotation often have different sets of connotations. Every translation, therefore, is an interpretation that emphasizes some potential meanings while muting or eliding others. Interpreters tend to smooth out fragmentary, complete, or incoherent statements, and so may mask thought disorder or other idiosyncrasies of speech with diagnostic relevance. The clinician needs to understand the choice of alternatives made by the interpreter in order to appreciate the connotations of the patient’s words and to convey his or her own nuanced meanings. These requirements place much higher demands on interpreting in mental health than in other medical or legal settings.

A slightly different model views the interpreter as a “go-between.” In this approach, the interpreter takes turns interacting with clinician and patient to clarify what is being said and to find a means of conveying it. This model acknowledges the interpreter as an active intermediary and allows the interpreter some autonomy. The sequential dyadic interaction puts greater time and distance between clinician and patient. This demands that the interpreter has a high degree of clinical knowledge and interpersonal skill, which is possible when the interpreter has been trained as a clinician. Taking this autonomy further, the interpreter may be viewed as a cotherapist. In this approach, the interpreter with clinical skills develops his or her own working alliance with the patient. The interpreter may respond independently to the patient and initiate interventions. This sometimes happens because of language barriers, when patients may contact the interpreter to ask for help with practical issues.

Given the complexities of interpreting, we prefer to view the interpreter as a culture-broker who works to provide both the patient and the clinician with the cultural context

---

**Table 4–4 Guidelines for Working with Interpreters and Culture-Brokers**

**Before the Interview**
- Explain the goals of the interview to the interpreter
- Clarify the roles of interpreter and clinician, and the conduct of the interview
- Discuss the interpreter’s social position in the country of origin and local community as it may influence the relationship with the patient
- Explain the need for literal translation in the mental status examination (e.g., to ascertain thought disorder, emotional range and appropriateness, and suicidality)
- Ask for feedback when something is hard to translate
- Discuss etiquette and cultural expectations

**During the Interview**
- Arrange seating (usually in a triangle)
- Introduce yourself and the interpreter
- Discuss confidentiality and ask for patient consent to have this interpreter
- Look at and speak to the patient; use direct speech (“you” instead of “s/he”)
- Use clear statements in everyday language
- Slow down your pace; speak in short units
- Do not interrupt interpreter
- Clarify ambiguous responses (verbal or nonverbal)
- Ask patient for feedback to insure that crucial information has been communicated and to ask questions or express concerns that have not been addressed

**After the Interview**
- Debrief the interpreter to address any of their own emotional reactions and concerns
- Discuss the process of the interview, any significant communication that was not translated, including paralanguage
- Assess the patient’s degree of openness or disclosure
- Consider translation difficulties and misunderstandings
- Plan future interviews
- Work with the same interpreter/culture-broker for the same case whenever possible
needed to understand each other’s meanings. To do this, the interpreter must understand something of the perspectives, cultural background, and social positions of both patient and clinician, and appreciate the goals of the clinical task. Based on this knowledge, the culture-broker can enhance patient and clinician understanding of each other, and can help negotiate compromises when there are widely divergent understandings of a problem and its solutions.

Despite increasing recognition of the importance of adequate interpretation, many clinicians or institutions use lay interpreters who are directly available at no cost, usually family members (even children) or other workers within the institution. Except in emergency situations, this practice should be avoided both because it exerts a strong censorship on what may be disclosed in the encounter and because it may damage relationships that are very important to the patient by transgressing social and familial boundaries.

Both interpreters and culture-brokers need training to perform competently, and clinicians need training, in turn, to work with these allied professionals. The clinician must take a systemic approach, understanding the other people in the room as part of an interactional system. Clinicians must also understand the interpreter’s position in the larger community. Some of this training can go on when clinicians have an opportunity to work repeatedly with the same interpreters, who thus become part of a treatment team. A culture broker with clinical skills can use their identity and intimate knowledge of the patient’s culture to position themselves in ways that foster communication and a strong therapeutic alliance (Clinical Vignette 9).

Clinical Vignette 9

A 42-year-old man from the Congo is referred for psychiatric consultation because of the concern that he is depressed following chemotherapy for leukemia. The patient lies in bed staring out of the window and complaining of poor appetite, headache, and fatigue. At first, he says little to the Euro-Canadian interviewer. After a few minutes of stilted conversation, the culture-broker, a psychologist from Central Africa, stands at the foot of the bed and delivers a lecture full of exhortations to the patient. He explains that the doctor has come to help, urges the patient to cooperate with the doctor, and insists that he must try to get better. After this intervention, the patient speaks more openly, clarifying that his fatigue and poor appetite are not due to depression or the lingering effects of chemotherapy, but stem from the absence of appropriate African food in his diet and the fear that he will die an improper death, far from home. His symptoms improve markedly once suitable food is arranged by contacting some supportive members of his cultural community.

Culture and the Stigma of Mental Illness

Stigma refers “to an attribute that is deeply discrediting” that marks the person as different from others and “of a less desirable kind” (Goffman 1963). Stigmatization occurs through processes of labeling, stereotyping, separation, status loss, and discrimination in a situation of differential power that allows one group of individuals to negatively label and devalue another (Link and Phelan 2001). Any socially marked characteristic of individuals can be used to assign stigma, including age, gender, physical appearance, behavior, national origins, accent, illness, or disability. It is thus not uncommon for individuals to suffer multiple forms of stigma that may interact in complex ways.

While most theories of stigma emphasize the psychological processes of stereotyping and social exclusion, social structural models show how some forms of prejudice and discrimination arise at the institutional level and reflect larger social, economic, political, and historical forces (Corrigan 2004). Examples of structural discrimination include legislation that restricts the rights of the mentally ill or media representations of negative stereotypes of people with mental illness (e.g., as dangerous or unpredictable).

Cultural explanations for psychiatric disorders, particularly causal attributions for symptoms or behaviors, influence whether stigma is attached to an individual with a particular disorder. Psychiatric labeling itself provides a particular interpretation of illness, and may be a major source of stigma. The meaning of the label depends on wider cultural systems of meaning. For example, initial hopes that giving biological explanations for mental disorders would reduce stigma have proved overly optimistic (Angermeyer and Matschinger 2005). In many cultures, the notion that an illness is biological means that it is intrinsic to the person and probably hereditary. This then leads to great stigmatization of the afflicted person, as well as their siblings and family who may find their prospects for marriage and social status significantly reduced. Fear of stigma by patients or other family members may be a major obstacle to help-seeking and treatment adherence. These considerations point to the importance of carefully assessing the potentially stigmatizing meanings of symptoms, behaviors, diagnostic labels, and treatment interventions. This assessment should extend beyond the patient to include attention to the meanings of the illness to others since they are the ultimate sources of stigma and social exclusion or acceptance and integration.

In most developing countries, psychiatry is associated only with the most severe chronic disorders and involves asylum treatment (Cohen 1988, Desjarlais, et al. 1995). Psychiatric disorders are highly stigmatized and the diagnosis of a family member may have negative effects on the social position of siblings and others. In contrast, common disorders like depression and anxiety are more likely to be understood as problems in living or sociomoral dilemmas that are not appropriate to be brought to a doctor or health professional (Kirmayer 1989). This is illustrated in Clinical Vignette 10.

Several issues touched upon in the interview may explain Mr. A.’s decision to not follow through with crisis intervention. He attributed the cause of his symptoms to his marital separation and, therefore, thought that an appropriate solution would be an intervention to help him to regain control over his situation by convincing his wife to rejoin the marriage. He did not see how “just talking” to a psychiatrist could solve his problem. Beyond this pragmatic focus on his social predicament, cultural factors may have played a role in Mr. A.’s reluctance to follow through on psychiatric treatment for his depression.
In Trinidad in the 1980s, the depression and demoralization felt by a man who had been betrayed or abandoned by an unfaithful wife might be understood as a problem of tabanka, an indigenous concept of reactive depression (Littlewood 1985). While the signs of tabanka may include the typical vegetative symptoms of depression, it has specific social meaning. Tabanka tends to elicit ridicule rather than solicitous concern from others, since the affected man is seen as “weak of mind” and his suffering a sign of embarrassing vulnerability or subordination to another. As a result, it is humiliating to seek outside help for this predicament—one is expected to overcome it alone. Also, psychiatric services in Trinidad are primarily associated with the treatment of severe psychotic disorders. For Mr. A. then, seeing a psychiatrist for the distress caused by his wife leaving him poses the threat of ridicule and damage to his reputation or social standing, as well as aggravating his feelings of loss of control. It is possible that a strategy in the ER consultation based on identifying these issues and mobilizing appropriate social support would work better than a referral for treatment of his depressed “state of mind.”

This case illustrates multiple barriers to delivery of mental health care: the stigma associated with psychiatric diagnosis and treatment, the conflict between specific cultural understandings of problems and biomedical theories, and the difficulty in offering services in a form that makes cultural sense and will enhance the individual’s social standing and functioning. Responding to these barriers begins before the clinical encounter and continues through the diagnostic assessment and the whole course of treatment. The process of framing and labeling patients’ problems must be done in a collaborative fashion that takes into account the social meanings and dilemmas posed by a particular diagnosis.

Conclusion: The Limits of Culture

The cultural formulation and the basic strategies of cultural competence represent useful initial approaches to exploring clinically relevant dimensions of patients’ cultural backgrounds. However, to apply these tools successfully, the clinician must avoid some biases implicit in psychiatric assessment and in the concept of culture itself.

Psychiatric diagnosis tends to be individual-centered, locating problems inside the individual, in their psychology, or neurophysiology. Cultural psychiatry, in agreement with family theory and therapy, recognizes that many problems are systemic and reside in interpersonal interactions or social contexts.

In cultural formulation, culture tends to appear as something distinctive of patients who come from ethnocultural minorities, migrants, or indigenous peoples. The clinician too has a culture that is distinctive from the patients’ point of view. Indeed, culture also constitutes the larger social matrix in which the clinical encounter is embedded. The cultural critique of psychiatric theory and practice are important correctives to this view of culture as something only possessed by the “other.”

Talk of culture tends to reify and essentialize it as a fixed set of traits or characteristics shared by all members of a group. However, there is enormous diversity and individual variation within any cultural group, and many divergent perspectives. The integrated whole of culture then appears to be a fiction or idealization. Contemporary anthropologists have argued for entirely dispensing with the notion of culture or else viewing it as an abstraction for a shifting set of perspectives, discourses, and resources used by individuals and groups to construct and position socially viable selves (Kirmayer 2006). This perspective recognizes that cultures are flexible frameworks that provide both opportunities and constraints but do not wholly determine the trajectories of individual lives.

With these caveats in mind, the clinician can apply the cultural formulation by approaching each case as unique, with a focus on the social and cultural context of the behavior and experience of the identified patient and his or her family (Kleinman and Benson 2006). Cultural competence involves using one’s knowledge of culture, language, and etiquette as modes of inquiry rather than as a priori answers to the dilemmas of a specific case. With the help of cultural experts, the clinician can appreciate the range of variation in a cultural group and its significance for individuals and the community. In this way, it is possible to recognize when culture is a camouflage for problems at other levels and when it itself is constitutive of problems. In assessment, the aim is to formulate cultural dynamics as part of a comprehensive process model of pathology. This can then be used to design interventions to address the most flexible or accessible level of the individual, family, or social system. Whenever possible, clinical interventions should mobilize and work with the family and ethnocultural community, who will have their own strategies and resources for problem solving and coping with adversity.

Cultural competence is based on respect for and interest in difference. It requires that clinicians become familiar with and comfortable talking about cultural differences rather than attempting to “treat everyone the same” in a misguided sense of “color blindness” or “neutrality”; lack of recognition of important differences results in ethnocentrism, seeing the world strictly from one’s own cultural point of view. Instead, the clinician must learn to decenter, to encounter the other on a more equal footing that allows questioning the cultural assumptions built into psychiatric practice. The language of competence is comfortable for clinicians because it suggests that we can add to our skills to
master another domain of expertise. But cultural competence goes well beyond refining our technical approaches, to demand that we examine our place, as individuals and practitioners, in the larger social and historical contexts that shape our relationships with patients.

Mainstream care cannot respond adequately to the needs of a diverse population unless it gives explicit attention to cultural issues. The ethnocultural diversity of mental health professionals represents an invaluable resource. Training programs must recognize this and make it safe for clinicians to explore their own ethnocultural background and assumptions as a path to more sensitive and responsive work with others.

Introduction
In the last several decades, advances in psychiatry have made it possible to treat mental disorders that were previously unamenable to successful intervention. There has been a dark side to this progress, however, because futuristic anticipation of subduing disease and forcing nature to surrender up her secrets, has led many practitioners to outrun their headlights. Like technical sorcerers of science-fiction confusing promise with reality, we are in danger of being lulled into an intellectual arrogance that can cause us to forget what it means to be professionals. One manifestation of this process has been the defensive reliance by clinicians on reductionistic explanations for complex and multi-determined disorders, combined with a neglect of the important role of trust and empathy as a curative factor in treating mental disorders.

A bewildering potpourri of treatment options and methods for financing health care present psychiatrists with other sources of confusion. Patients’ health and safety often depend upon our ability to make rapid clinical decisions regarding diagnosis, and to utilize an optimal psychotherapeutic or psychopharmacologic approach. The psychiatrist’s dilemma is similarly compounded by conflicts between the cost-determined restrictions of managed care, versus the sacred promise to advocate primarily for patients’ welfare. Building a cooperative and trusting relationship with patients has always been an essential factor enabling clinicians to foster the healing process. In ancient times, when there were few specific remedies available, physicians relied on a highly integrative view of the sick person. For example, ancient Egyptian medicine did not make a special distinction between soma and psyche in considering physical and mental disorders, and therefore attached no special stigma to the mentally ill (Okasha and Okasha 2000). Similarly, the rabbinic sage and physician, Moses Maimonides (1135–1204 A.D.) (1944), relying on scriptural and clinical wisdom, taught that both physical and mental illness resulted from imbalances in somatic and mental processes, and that physical health and mental health are interdependent (Gorman 2001).

In most instances, modern technology augments but cannot substitute for a trusting doctor–patient relationship. Patients seeking medical care must suspend ordinary social distance and critical judgment if they are to allow physicians to enter their physical and psychological space. While neither the law nor medical ethics relieve patients from taking an active responsibility for treatment outcome (American Medical Association 1993), society places a greater burden upon the healer—a mandate to act with the special care and vigilance expected of a fiduciary (Frank and Frank 1991), (Simon 1987) or of a Common Carrier (Epstein 1994, pp 59–61), as a precondition for granting licenses to practice.

As we review in this chapter, the ability to sustain a professional attitude, and to practice within a set of coherent boundaries, forms the foundation of proper psychiatric treatment, regardless of theoretic orientation or treatment modality. An understanding of psychiatric ethics plays a vital role in the psychiatrist’s ability to keep proper boundaries because these values provide a stable beacon in the cognitively perplexing fog that so often pervades the treatment situation.

Ethical Behavior and Its Relationship to the Professional Attitude
The term professional derives from medieval times, when scholastics were expected to “profess” their belief in a doctrine (Dyer 1988 p 17). In modern times, a professional is expected to be a learned person who has acquired special knowledge of a subject that is of vital importance for the welfare of the community. Having expertise is not enough, however. A professional is also obliged to adhere to certain societal responsibilities that are founded upon a code of ethical behavior, and an attitude of service to those in need. A professional commitment to ethical behavior and service must take precedence over monetary compensation (Dyer 1988, p 16). All physicians, including psychiatrists, are...
bound by such a covenant—a sacred vow to place patient well-being before other considerations (Webb 1986).

**General Principles of Medical Ethics**

In western tradition, the canon of medical ethics derives primarily from the teachings of Hippocrates, a Greek physician from the Island of Cos, who practiced Medicine in 5th century B.C.E. Hippocrates’ Oath is the predominant pledge recited at the graduation exercises at American medical schools (Dickstein et al. 1991), and contains three of the six core principles of modern medical ethics, including beneficence, non-malfeasance, and confidentiality:

I will follow that system of regimen which according to my ability and judgement, I consider for the benefit of my patients, and abstain from whatever is deleterious and mischievous … With purity and holiness I will pass my life and practice my Art … Into whatever houses I enter, I will go into them for the benefit of the sick, and will abstain from every voluntary act of mischief and corruption; and, further, from the seduction of females or males, of freemen and slaves. Whatever, in connection with my professional practice or not, in connection with it, I see or hear, in the life of men, which ought not to be spoken of abroad, I will not divulge, as reckoning that all such should be kept secret (Hippocrates 1929).

The other three general principles of medical ethics include autonomy, justice, and veracity (see Table 5–1 for a description and summary of all six ethical principles (Epstein 1994, p 20).

**Psychiatric Ethics**

Radden (2002) reasoned that the emotionally charged interpersonal process that often plays such a key role in psychiatric treatment, necessitates a unique and generally more stringent ethical system than the basic principles of medical ethics. Psychiatric patients are especially vulnerable during treatment, to such extent that the ethical character of the psychiatrist has a unique and powerful potential to help or to harm our patients. By working to enhance their own positive character traits, psychiatrists improve their potential to be able to be helpful. Positive character virtues that are likely to enhance the effectiveness mental health professionals include compassion, humility, fidelity, trustworthiness, respect for confidentiality, veracity, prudence, warmth, sensitivity, perseverance, patience, and generosity (Radden 2002).

In keeping with its status as a medical specialty organization, the American Psychiatric Association (APA) (American Psychiatric Association 1973) adopted the American Medical Association’s (AMA) Principles of Medical Ethics as the underlying basis of its canon of ethics. APA solved the problem of psychiatry’s unique requirements by adding special annotations applicable to psychiatric practice, to the AMA Principles of Medical Ethics.

The APA has produced six revisions of these annotations. The seven sections of the AMA principles are summarized in Table 5–2. Table 5–3 summarizes some of the salient APA ethical annotations for psychiatrists (American Psychiatric Association 1993).

International Guidelines Psychiatric Ethics

The World Psychiatric Association (WPA) (World Psychiatric Association 1999–2002), (World Psychiatric Association Ethical Statements 2000) developed and approved ethical guidelines, starting with the Declaration of Hawaii in 1977, galvanized by concerns about the abuse of Psychiatry. A long process of investigation within the domain of professional ethics, provided the foundation for the Declaration of Madrid that was endorsed by the General Assembly of the World Psychiatric Association in 1996. In its final form, the Declaration of Madrid included seven general guidelines that focused on the aims of psychiatry (World Psychiatric Association 1999–2002; World Psychiatric Association Ethical Statements, 2000). They are summarized as follows:

**Summary of Ethical Principles in the Declaration of Madrid**

1. Psychiatry’s concern should be to provide the best treatment and rehabilitation for persons with mental disorders, consistent with scientific knowledge, ethical principles, and with the least possible restriction on the freedom of the patient.

2. Psychiatrists have a duty to keep abreast of scientific developments. Psychiatrists trained in research should seek to advance the frontiers of knowledge.

3. The psychiatrist–patient relationship must be based on mutual trust and respect, and should allow the patient make free and informed decisions. The psychiatrist has a duty to accept the patient as a partner in the therapy and to empower the patient with necessary information for rational treatment decisions.

4. Psychiatrists should consult with families of incapacitated patients to safeguard the human dignity and the legal rights of the patient. Treatment should not be given against the patient’s will, unless withholding treatment would endanger the life of the patient or others. Treatment must always be in the best interest of the patient.

5. Psychiatrists performing assessments, especially when retained by a third party, have a duty to inform the person being examined about the purpose of the intervention, the use of the findings, and the possible repercussions of the assessment.

6. Unless there is a threat of serious harm to the patient or other persons, psychiatrists should keep all patient information in confidence, and use such information only for the purpose of helping the patient. Psychiatrists are prohibited from making use of such information for personal, financial or academic benefits.

7. It is unethical to conduct research that is not in accordance with the canons of science. Research activities should be approved by an appropriate and ethically constituted oversight committee. Because of the vulnerability of psychiatric patients, extra caution and strict ethical standards should be employed to safeguard patients’ autonomy, patients’ mental and physical integrity, and the selection of population groups.

An appendix in the Declaration of Madrid includes additional guidelines on specific ethical issues in psychiatry, including the following (World Psychiatric Association 1999–2000; World Psychiatric Association Ethical Statements 2000):

* WPA Guidelines on Euthanasia
The physician’s role first and foremost, is to promote health, reduce suffering and protect life. The psychiatrist, whose patients may include those who are severely incapacitated or incompetent to reach an informal decision, should be particularly careful about actions that could lead to the death of individuals who cannot protect themselves because of disability, and should be vigilant to the possibility that a patient’s views could be distorted by mental illness such as depression. In such situations, the psychiatrist’s role is to treat the illness.

* WPA Guidelines on Torture
A psychiatrist should not take part in any process of mental or physical torture, even when authorities attempt to force their involvement in such acts. Furthermore, a psychiatrist should not participate under any circumstances in legally authorized executions, nor participate in assessments of competency to be executed.

* WPA Guidelines on Sex Selection
It is unethical for a psychiatrist to participate in decisions to terminate pregnancy for the purpose of sex selection.

* WPA Guidelines on Organ Transplantation
Psychiatrists should seek to protect their patients and help them exercise self-determination to the fullest extent possible. The role of the psychiatrist is to clarify the issues surrounding organ donations and to deal with the religious, cultural, social, and family factors to ensure that informed and proper decisions be made by all concerned.

* WPA Guidelines on Genetic Research and Counseling in Psychiatric Patients
Psychiatrists participating in genetic research should be mindful that the ramifications of genetic information are not limited to the individual subject or patient, but can lead to far reaching repercussions and consequences that can have a negative and disruptive effect on the larger family or community. Psychiatrists are ethically obligated to observe proper practice, avoid the risks associated with premature disclosure, misinterpretations, or misuse of genetic information, and should never advise a pregnant woman with mental disorders to get an abortion based on the medical or genetic basis of their mental illness. They should not refer patients to genetic testing unless there are satisfactory levels of quality assurance and adequate genetic counseling available to the patient.

Further guidelines on the relationship between psychiatrists and the media, ethnic discrimination, ethnic cleansing, and genetic research and counseling were endorsed by the WPA General Assembly in 1999:

* WPA Guidelines on Ethnic Discrimination and Ethnic Cleansing
The Madrid Declaration defines ethnic discrimination as basically racist, as it fails to accept diversity and humanity’s common heritage. In its most malignant form, ethnic cleansing is a crime against humanity. In this regard,
psychiatrists should not discriminate nor help to discriminate against patients on ethnic grounds, nor be involved in any activity that promotes ethnic cleansing.

• WPA Guidelines on Psychiatrists Addressing the Media
It is important that psychiatrists use the media in an affirmative way for a variety of goals that promote good mental health care such as advocating for the destigmatization of mental disorder and mental patients. In all their interactions with the media, psychiatrists are obliged to advocate for the mentally ill and to maintain the dignity of the profession. Psychiatrists should be mindful of the effect of their statements on the public perception of the profession and patients, and abstain from making statements or undertaking public activities that may be demeaning to either. Patients’ confidentiality should be maintained, and the sensationalization of mental illness should be avoided. Regarding the disclosure of research findings, psychiatrists should cautious to report only results that are generally accepted by experts, and to convey the presentation of such results in a way that serves patients’ welfare and dignity.

Ethical Principles Applicable to Forensic Psychiatrists
A controversy exists regarding the ethical duties of forensic psychiatrists in settings where the sole and explicitly stated function of the psychiatrist is to conduct an examination of an individual for the purpose of providing a report or testimony during legal proceedings. According to Arboleda-Florez (2006), one point of view, sometimes termed the “English position,” considers forensic psychiatry to be just another medical specialty, in which case the psychiatrist is fully bound by the principles of medical ethics. Another point of view, known as the “American position,” argues that a forensic psychiatric examination is conducted under the aegis of a legal process and is not a medical procedure. Prior to the forensic interview, the examinee is informed that the sole purpose of the examination is to report psychiatric findings to a third party, usually some type of legal or administrative forum. According to the latter position, no treatment relationship is ever established, and the sole ethical obligation of the forensic psychiatrist is to seek and report the truth in the interest of serving justice for the common good of the community. As stated by Appelbaum (1999), the forensic psychiatrist does not establish a physician–patient relationship with the examinee, and is therefore bound primarily by the ethical principle of justice, and not the pursuit of health. He cautioned that attempts to maintain a semblance of the physician–patient relationship and its ethical requirements during forensic psychiatric examinations would lead to role confusion for both parties and difficulties with dual agency.

Gaughwin (2004) reviewed the relationship between federal court rules in Australia, and Practice Guideline No. 9 of the Royal Australian and New Zealand College of Psychiatrists. He cited Practice Guideline No. 9.2.3, that states that the psychiatrist must strive for honesty and objectivity regardless of who retained the psychiatrist, and that the psychiatrist should take care not to act in the role of an advocate in reporting. Thus, even if the psychiatrist feels strong empathy for the distress of the individual being examined, in accepting the role as a forensic expert, the psychiatrist must be prepared for the potential that his or her opinion might be adverse to the wishes of the examinee, and may be very different than the role that would be taken if the examinee was a patient in treatment with the examiner.

Sarkar and Adhead (2002) outlined some of the ethical complexities inherent in the forensic psychiatrist’s role. Despite the fact that medical experts are legally immune with regard the content of their testimony in a judicial forum, the professional expectations placed on psychiatrists as health care professionals by judges, juries, and litigants is such that they could still be held to account for their conduct in a forensic examination or report, particularly if they were negligent in the manner by which they conducted their examination.

Tarboda and Abdalla-Filho (2002) concluded that improvement is needed in developing coherent ethical guidelines for forensic psychiatrists in their role as experts who report or testify in a third-party forum. Issues they cited included concern about experts who appear to sell their opinions like “hired guns,” and the need for experts to guard against incomplete and biased testimony arising from unconscious identification with the side that retained the examiner’s services.

Forensic psychiatrists should be aware that an examination by a skilled psychiatrist can have a powerful emotional effect on the examinee, even if unintended. This effect is engendered by the subtle vulnerabilities mediated by a relaxation of defenses on the part of the examinee, and can occur despite the examinee having been informed that the interview is solely for legal testimony and not for treatment. Lowering of psychological defenses is particularly likely to occur with examinees that have experienced previous psychiatric treatment. Such individuals have often developed embedded feelings of trust that lead them to view psychiatrists in general, as friendly and benevolent individuals whose primary goal is to help them feel better. For this reason, forensic psychiatrists should endeavor assiduously not only to maintain a respectful and professional demeanor during forensic examinations, but to be particularly alert to any tendency to exploit an examinee’s tendency to transform the exam into a treatment session, or to use the authoritative aura of psychiatrist to shame or trick the examinee during the exam much like a cross-examining attorney might try to impeach an adverse witness during a trial. These caveats are especially important in situations where the forensic psychiatrist has been hired by a party taking a position adverse to the examinee’s legal claims.

In situations where it is possible to do so, examiner bias is likely to be reduced if the forensic psychiatrist obtains a retainer fee in advance. This reduces the financial threat of withheld payment if the expert’s opinion turns out to be adverse to the side that retained the expert. The examiner’s desire to satisfy the hiring attorney or agency in order to be retained for future cases is another potential source of bias. This bias is best handled by striving for integrity rather than trying to please the retaining party. Other sources of bias occur when a psychiatrist takes on a dual role by attempting to take a forensic examinee into treatment, or alternatively by endeavoring to testify as a forensic expert with a current patient who is in ongoing treatment with the psychiatrist (Epstein 1994, Chapter 7; see also Subsection “Avoiding Dual Relationships” below).
Forensic psychiatrists should strive for honesty and objectivity by conducting a meticulous and thorough examination. This examination should, if possible, include interviews with other persons who have collateral knowledge of the examinee or of other factual information pertinent to the case, as well as full review of all available medical and legal documents. During the interviews with the examinee, interviews with collateral informants, and in the formulation of expert psychiatric opinions, the psychiatrist should take a skeptical mental stance and try to avoid prematurely jumping to conclusions. Instead, the expert should weigh the entire realm of logical possible alternatives that could explain the clinical findings as they unfold during the evaluation process. In this way, the forensic psychiatrist’s ultimate opinion is refined in the crucible of an internal adversarial dialogue in a way that is likely to reduce bias and increase objectivity.

**The Coherent Treatment Frame and the Role of Therapeutic Boundaries in Effective Psychiatric Treatment**

The “frame” of a social interaction was defined by Goffman (1974), as consisting of the spoken and unspoken expectations defining meaning and involvement in a given situation. For example, patients seek out psychiatrists based on a tacit assumption that the doctor is a reliable and experienced clinician who has the ability to assist them in finding relief for distress. However, many patients tend to frame their treatment in pathological ways. For example, some will attempt to pressure the psychiatrist into the role of a magical wizard who will confer unconditional love and pleasure. Whatever method the patient employs to frame the relationship, any abrupt disappointment or rupture of these unspoken expectations often results in intense and disruptive feelings of mortification and betrayal. A sudden breach of a social frame can lead to the dissolution of one’s sense of meaning and connection, and is often accompanied by intense feelings of shame. By examining verbal and behavioral responses following violations of the treatment frame, Langs (1984–85) was able to document that patients usually perceive the offending therapist as an unreliable and mentally unstable person—someone seeking perverse pleasure at another person’s expense.

The psychiatrist’s task is to provide a coherent therapeutic frame within which to contain the patient’s illness. The psychiatrist’s frame makes it secure to proceed with the specific therapeutic modality, just as the surgical suite provides a safe environment for operative techniques. The treatment frame enables the patient to maintain a feeling of trust and connectedness while learning to deal with the unrealistic nature of his/her expectations. The frame is comprised of various boundary factors that include acting in a reliable way; showing respect for the patient’s autonomy by explaining the potential risks and benefits of the treatment method; maintaining confidentiality; avoiding exploitation of the patient’s sexual feelings; and resisting the patient’s manipulative efforts by explaining the maladaptive nature of such behavior (Epstein 1994, Simon 1992).

Frank and Frank (1991) conducted an extensive review of the literature concerning psychotherapy outcome. They determined that there were four basic factors common to all successful psychotropes (see Table 5–4), and that treatment efficacy relied upon the ability of the therapist to form a structured, mutually trusting, confidential, and emotionally arousing relationship. Their findings sustain the argument that maintaining a coherent treatment frame is an essential part of all psychiatric treatment, regardless of the therapeutic paradigm being employed. These issues are important whether the patient is being treated solely with psychotropic medication management, cognitive/behavioral therapy, or psychoanalysis.

**Boundary Violations**

Psychiatric treatment cannot be conducted without doctor and patient entering into each other’s space, just as it is impossible to perform a bloodless laparotomy. Gutheil and Gabbard (1993) termed such incursions occurring during the therapeutic process as “boundary crossings.” They defined boundary violations as “boundary crossings” that cause injury to the patient. However, it is not always easy to be sure of the consequences of such a “crossing,” since harmful effects may be delayed or concealed. Many patients are unable to articulate their sense of injury because the psychiatrist’s aberrant behavior may appear so similar to exploitation they have experienced in previous pathological relationships. For example, patients who were sexually abused in childhood are more likely to acquiesce to an amorous advance by a psychiatrist, and to avoid complaining about feeling used, because they fear the threat of the psychiatrist’s rejection and retaliation. Certain non-sexual boundary crossings such as conflicts of interest might seem harmless on the surface, but can interfere with patients’ ability to feel safe in their psychiatrist’s care, and will diminish their chances for optimal recovery. In this context, a boundary violation can be defined as any infringement that interferes with the primary goal of providing care, or causes harm to the patient, the therapist, or the therapy itself (Epstein 1994, p 2).

Prior to the 1970s, open discussion of the topic of psychiatrist–patient sex was virtually taboo, and considered “too hot to handle” as a subject for publication in scientific journals (Dahlberg 1970). Professional societies demonstrated an inconsistent and ambiguous attitude of “amused tolerance” (Pope and Bouhoutsos 1986, p 161) towards mental health practitioners engaging in sexual behavior with their patients.

The public has become increasingly interested in the subject of psychiatric boundary violations in the past 25 years, particularly those involving sexual exploitation. State licensing boards, professional ethics committees, and civil juries are much more likely to mete out strong sanctions...
against violators than ever before. These attitudinal changes have taken place in spite of the fact that popular movies continue to romanticize the idea of psychiatrist–patient sexuality, and almost always seem oblivious to the horrendous feelings of shame, betrayal, and devastation that patients experience when these things happen to them in real life.

One reason for the public’s intolerance of sexual involvement between psychiatrists and patients has resulted in part from the increasing empowerment of the victims of incest, rape, and spousal abuse, and a better understanding of the psychological sequelae that follow mental trauma such as posttraumatic stress disorder (PTSD). In addition, psychiatric patients have become more willing to expose unethical or exploitative behavior on the part of clinicians, particularly, when it involves sexual activity. This trend has been augmented by the fact that courts and professional licensing bodies are now more inclined to render sanctions for injuries that are solely psychological in nature.

Quantitative estimates of the frequency of sexual boundary violations among mental health professionals derive from survey studies conducted over the last 20 years (Pope and Bouhoutsos 1986, Kardener et al. 1973, Perry 1976, Holroyd and Brodsky 1977, Gartrell et al. 1986, Bors and Pope 1989, Schoener 1990). A review of these studies shows that from 5.5−13.7% of male mental-health clinicians admit to engaging in sexual activity with patients. Epstein (1994, pp 207–208) calculated a crude weighted average from Schoener’s (1990) comprehensive review of survey studies reporting frequency of sexual violations by clinicians’ gender. From ten studies involving a total of 5,816 respondents (excluding a large survey of nurses) an average of 7.4% of male and 2.3% of female clinicians admitted to engaging in sexual behavior with patients. These data suggest that male clinicians are about three times more likely to admit they have become sexually involved with patients. Although more recent studies suggest that sexual exploitation by mental health practitioners might be occurring less frequently, increasing media reports of severe sanctions taken against offending therapists has probably diminished the validity of self-report questionnaires.

Studies of non-sexual violations suggest that many mental health clinicians still have serious problems maintaining professional boundaries with patients, (Bors and Pope 1989; Epstein et al. 1992). Epstein et al. (1992) queried 532 psychiatrists practicing in the United States about their behavior with patients within a prior 2-year period, using the Exploitation Index (EI) developed by Epstein and Simon (1990). They found that 19% of respondents reported engaging in a personal relationship with patients after treatment was terminated, 17% told patients the personal details of their life in order to impress them, and 17% joined in activities with patients to deceive a third party such as an insurance company (see Table 5–5, reviewing the frequency of non-sexual boundary violations among respondents in this study). Xiangyi and Tiebang (2001) surveyed mental health clinicians in China using a Chinese translation of the EI. They found a rate of endorsement of boundary violations that was similar to the findings in the US study, although there were distinct variations in the pattern of certain responses that the authors attributed to cultural differences between the two populations.

Simon (1989) emphasized that when clinicians engage in non-sexual infringements of the treatment relationship, it is often a prelude to subsequent sexual behavior. Sexual involvement with patients often starts with excessive personal disclosure, accepting and giving gifts, requesting favors, and meeting patients outside of the office setting. Like a seduction, the behavior escalates over time until it culminates in sexual contact (Simon 1989).

Source: Epstein et al. (1992).

Regardless of the specific type of infringement involved, there are common elements to all boundary violations. Peterson (1992) argued that such activity emanated from a disturbed and disconnected relationship. She suggested four basic behavioral themes in this regard, including efforts on the part of the clinician to reverse roles with the patient, to intimidate the patient to maintain secrecy, to place the patient in a double-bind, and to indulge professional privilege. Indulgence of privilege is often accompanied by a sense of entitlement on the clinician’s part, such that he/she regards the patient as a wholly owned subsidiary.

Epstein (1994, pp 89–110) outlined the progression of boundary violations as they originate from dysregulation in the clinician’s personal ego boundaries. Circumstances impairing the clinician’s ability to cope with patients and their problems may include deficient knowledge, general stress, mental disorder, or a treatment induced regression. These factors may lead the clinician to employ maladaptive intrapsychic or behavioral coping mechanisms that manifest in the form of therapeutic boundary violations. Other general factors common to all boundary violations include a slippage of the original purpose of the treatment (Epstein 1994, pp 97–98), pseudo-eclecticism (Epstein and Janowsky 1969), a narcissistic sense of specialness (Epstein 1994, pp 107–110, Epstein and Simon 1990), and efforts to de-professionalize the relationship by fostering an atmosphere of “pseudo-equality” between clinician and patient (Peterson 1992).

The double-binding messages that exploitive clinicians employ often represent a way for them to project their own disavowed feelings of shame and inadequacy onto vulnerable patients. For example, a therapist may decide a patient suffering from low self-esteem and sexual dysfunction by encouraging her to have sex with him. He may rationalize:

You have told me that you feel unattractive and inadequate as a woman. Since therapy is supposed to help you with your problems, I will help show you how attractive and effective you are as a woman by having sex with you.
Psychotherapy and erotic behavior can both be construed as sub-categories of the superordinate class of "Activities that help people feel better" (Epstein 1994, p 102). In the example above, the exploitive therapist blurrs the logical boundaries between the two sub-categories, and fails to inform the patient that sexual behavior with him is likely to be harmful to her. Blurring of logical categories is an essential aspect of double-binding messages. Patients who are subjected to such reasoning are often in a dependent and cognitively regressed state, and are unable to understand the logical absurdity of the double bind. They fear that if they refuse to comply with the therapist’s suggestions, they will be rejected for failing to cooperate with the therapist.

It is important to place the burgeoning literature on boundary violations in its social context. An aroused public has been exposed to recurring reports of psychiatrists and other mental health professionals, who have been disciplined or sued for behavior such as sexual involvement with patients and spouses of patients; using information learned in patients’ psychotherapy sessions to gain inside data on financial investments; and accepting large bequests from elderly patients. Each new scandal serves to erode society’s trust in the integrity of psychiatry as a profession, and makes it more difficult for the mentally ill to obtain needed treatment. Compounding this problem is the fact that many of these well-publicized reports of boundary violations involved highly trained psychiatrists who were leaders in their field, and who served as important role-models for students in professional training.

As has occurred many times before in history, societal changes tend to over-shoot the mark, leading some observers to caution against an hysterical “witch hunt” against suspected offenders. Slovenko (1991) cautioned that the current climate has become ripe for an increasing number of false accusations to be made against innocent clinicians. Gutheil (1992) has documented such cases, and provided guidelines for proper forensic psychiatric evaluation following allegations of sexual misconduct.

### Components of the Coherent Psychiatric Frame

The purpose of the therapeutic frame is to protect the patient’s safety and to promote recovery. It is the therapist’s responsibility to structure the frame through word and deed. Langs (1984–85) stressed that a healthy and secure therapeutic environment is predicated on reducing variability and uncertainty in the treatment setting as much as possible. Table 5–6 summarizes the major boundary factors comprising the coherent treatment frame. Careful attention to these boundary issues can assist treating psychiatrists to communicate defining messages that strengthen the differentiation of role and identity between patient and practitioner.

The diversity of opinion regarding optimal methods of treatment for specific psychiatric disorders makes it very difficult to devise a set of specific guidelines that are appropriate for psychiatrists adhering to a wide spectrum of theoretical orientations. Dyer (1988; pp 45–57) emphasized how problematic it is to define a comprehensive ethical system, whether it is based on a set of specific rules (deontological ethics), on a list of values and goals (teleological ethics), or from consideration of the emotional and practical consequences of a given course of action (consequentialist ethics). A parallel dilemma exists when it comes to defining psychiatric boundaries.

### Table 5–6 Major Boundary Issues Contributing to the Formation of a Coherent Treatment Frame

<table>

<td>Discourages the patient’s destructive behavior, sets a good role-model for establishing healthy self-esteem</td>
<td>“It is possible to have a close relationship without someone getting hurt.”</td>
</tr>
</tbody>
</table>

For this reason, guidelines for psychiatrists should enhance patient safety, foster adherence to established clinical principles, and help to avoid specific consequences that are detrimental to either patient or practitioner. Such an approach is consistent with an intensifying interest in reducing preventable medical error. In his seminal work on human error, Reason (1990, p 69) outlined three major types of performance as a way to address the sources of preventable human error. These categories include rule-based performance, skill-based performance, and knowledge-based performance. As an example, Reason described how the use of inadvisable rules leads to rare but preventable collisions at sea, citing studies reporting how experienced maritime
pilots expose themselves and others to unnecessary and potentially serious risk by allowing their own vessel to navigate too closely to adjacent ships even when there is plenty of sea room to avoid such proximity:

The confidences these and other experienced operators have in their ability to get themselves out of trouble can maintain inadvisable rule behavior. This is particularly so when a high value is attached to recovery skills and where the deliberate courting of a moderate degree of risk is seen as a necessary way of keeping these skills sharp.

With regard to rule-based procedures for reducing error in psychiatric practice, each boundary issue can be examined from the point of view of clearly indicated procedures, relatively risky procedures, and contraindicated procedures (Epstein 1994 pp 113–117). In the ensuing discussion of components of the psychiatric frame, lists of these various types of procedures are adapted from Epstein's earlier work on boundaries (Epstein 1994, pp 119–236).

Riskier procedures that fall into the “gray zone” are not necessarily unethical or unsound. However, psychiatrists engaging in such activity should be aware of the circumstances under which they increase or reduce the chance for injury either to the patient or themselves. For example, under most conditions, it is probably unwise to attempt psychiatric treatment of one's next-door neighbor. Nevertheless, practitioners living in remote areas, or working in confined ethnic communities, might as a matter of practicality, be forced to treat such a patient for whom no reasonable alternative exists. The hazard of no treatment may outweigh other factors in the situation. However, the fact that psychiatrists sometimes must treat patients under risky circumstances does not mean they should disregard the increased hazard they are assuming, or forget about optimal treatment standards, just as the exigencies of battlefield surgery do not obviate the need to strive for aseptic technique.

Psychiatrists should safeguard against any semblance of inappropriate behavior, even if the activity can be justified as seemingly harmless. For example, seeking social activities with patients outside of the treatment setting can be interpreted by patients or their family members as seductive. Gutheil and Gabbard (1993) have emphasized that the very appearance of undue familiarity with a patient, may in and of itself, hamper successful defense against false allegations of professional wrongdoing.

**Stability**

Configuring a stable and consistent treatment setting is analogous to the “holding environment” provided by parents in early childhood (Winnicott 1960). Patients with psychiatric illnesses will find it very difficult to entrust their lives to a psychiatrist whom they perceive to be unreliable. Indicated measures regarding stability include formulating an agreement with the patient for a treatment regimen that will take place according to a specific method and schedule; encouraging truthful disclosure and cooperation; establishing a commitment to beginning and ending sessions on time; discouraging interruptions during treatment sessions; offering advanced notice as to when the psychiatrist will be absent; providing for coverage by another practitioner when the psychiatrist is off duty; maintaining coherent therapeutic demeanor; and maintaining relative consistency as to who participates in the treatment session.

It is generally unwise for a psychiatrist to disparage a patient’s complaints about issues like the doctor’s tardiness in starting sessions, or to become defensive when explaining the meaning of the patient’s distress about such complaints. Many psychiatrists experience patients’ demands for consistency as a form of control and imprisonment. Out of anger, they may react to these patients as if their wishes for reliability and concern were infantile and irrational:

> Your complaints about my lateness are a reflection of your need to control me.

The psychiatrist’s tardiness might in fact be creating tremendous anxiety because it reminds the patients of parents who never took their feelings into account.

**Avoiding Dual Relationships**

Psychiatrists should avoid treatment situations that place them in a conflict between therapeutic responsibility to patients and third parties. Examples of dual relationships in psychiatric practice include clinicians treating their own relatives and friends; the same therapist employing concurrent family and individual therapy paradigms with a given patient; and clinicians testifying as forensic witnesses for current psychotherapy patients. Although it is very common practice (Epstein et al. 1992), accepting psychotherapy patients referred by one’s current or former patients referred to them in a conflict between therapeutic responsibility to the patient and personal motivations.

Many psychiatrists experience patients’ demands for consistency as a form of control and imprisonment. Out of anger, they may react to these patients as if their wishes for reliability and concern were infantile and irrational:

> Your complaints about my lateness are a reflection of your need to control me.

The psychiatrist’s tardiness might in fact be creating tremendous anxiety because it reminds the patients of parents who never took their feelings into account.

**Role conflicts are quite widespread (Pope and Vetter 1992) and interfere with the practitioner’s single-mindedness of purpose as a healer. Chodoff (1993, pp 457–459) placed special emphasis on this issue by arguing that advocating for the needs of the mental illness was one of psychiatry’s primary societal responsibilities. By eroding public trust, dual relationships interfere with the ability of psychiatrists to carry out their vital functions in the community.

The burgeoning expansion of prepaid care in the US over the last two decades has provoked concern about a new source of role-conflict for psychiatrists. Managed care has been espoused as an important modality to reduce unnecessary treatment by encouraging preventive care, and to promote cost-consciousness among physicians (Fries et al. 1993). Stephen Appelbaum (1992) argued that psychotherapists practicing under the old fee-for-service model were more inclined to provide unnecessarily prolonged treatment than those working under an organizational system that prevented direct monetary involvement between patient and practitioner.

On the other hand, increasing coverage of the population of the US under a system of managed care has generated serious concerns regarding potential conflicts-of-interest (McKenzie 1990, pp 113–126). This disquietude is particularly noticeable in the field of psychiatry. Many managed care organizations (MCOs) have severely restricted the number of psychiatrists within a given community allowed to serve on their treatment panels. Patients’ access to their
regular treating practitioner has been further limited, even when the doctor is allowed to enroll on the panel.

For example, under the rules of some MCOs, a psychiatrist might be prevented from maintaining continuity of care for outpatients needing hospitalization. During their hospital stay, such patients must be attended by a pre-selected group of psychiatrists who conduct all hospital treatment for the plan.

Although there are little scientific data to support the contention that restricted managed care panels are necessary for lowering costs, it is important that both patients and clinicians be informed as to the hazard such a system of care entails. Since participation on a panel is often contingent on cost-efficiency profiles, psychiatrists who derive a significant portion of their income from a given MCOs are discouraged from advocating for patients needing more expensive care. In addition, some managed care organizations refuse to pay for integrated treatment by psychiatrists for mentally ill patients enrolled in their panel. These MCOs insist instead on a split treatment model in which the patient obtains psychotherapy from a social worker or psychologist, and is allowed only brief medication management visits with a psychiatrist. Psychiatrists attempting to do medication management under this model often have little contact with the psychotherapist, are very restricted in the frequency and duration of visits with the patient, and are thereby limited in making overall clinical decisions that might become necessary. Such a situation creates an ethical bind for the psychiatrist in which the medical responsibility is not accompanied by a commensurate degree of authority to direct the treatment process.

In the face of reports of physicians claiming they were terminated from managed care contracts because they protested treatment denials, fear of retaliation for patient advocacy has mounted (McCormick 1994). Judge Atlas (1993) has suggested that psychiatrists who fail to give informed consent regarding the risks to the patient of their role conflicts would be exposing themselves to civil damages in the event of an adverse outcome. Although the extent of the legal duty to disclose risks factors under managed care is unresolved, Appelbaum (1993) proposed that mental health clinicians inform beginning patients that payment for treatment under managed care might be stopped before the patient feels ready to terminate.

Limitations as to who may serve on a managed care panel and what functions the clinician may perform, are other factors that have strong potential for creating disruption in the continuity of care. For example, Westermeyer (1991) described seven case histories in which psychiatric patients treated under managed care committed suicide or suffered serious clinical deterioration. Clinically uninformed managed care practices appeared to serve as critical aggravating factors for each of these patients. In the cases of two individuals who killed themselves, the employer had switched contracts to different managed care companies, and the patients were forced to transfer to new clinicians. These disruptions appeared to play an important role in the patients’ suicides.

Although more research is required to evaluate the full ramifications of managed care on psychiatric populations, recent studies suggest that some groups face adverse outcomes under this system. For example, Rogers et al. (1993) found that on an average, patients with depression who were treated by psychiatrists under pre-paid treatment plans acquired new limitations in their physical or day-to-day functioning over a 2-year period, while those treated in the traditional fee-for-service setting did not.

**Autonomy and Neutrality**

Freud (1912, 1913) recommended that psychoanalysts adhere to a position of neutrality with their patients by refraining from the temptation to take sides in the patient’s internal conflicts or life problems. This advice has relevance for all psychiatric treatment, insofar as it espouses the idea that practitioners should maintain profound respect for their patients’ autonomy and individuality. This is a fundamental therapeutic stance that fosters independence, growth, and self-esteem. It reinforces the idea that the clinician believes the patient to be the owner of his or her body, life, and problems. The patient receives the following message:

> The doctor tries to help by trying to take control of me.

Patient autonomy has not always been accorded its current importance in the hierarchy of priorities in medical practice in the United States. According to Blackhall et al. (1995), in 1961, 90% of physicians in the United States did not inform their patients of a diagnosis of cancer. By 1979, 97% of American physicians made it their policy to inform patients with cancer of their diagnosis (Blackhall et al. 1995). This change appears to be the result of physicians assuming less of a paternalistic attitude, and becoming more enlightened and respectful of patients’ right to participate in medical decisions. In some parts of the world, similar changes have occurred in clinical practice with mentally ill patients.

Cultural, ethnic, and probably sociodemographic factors strongly shape attitudes regarding patient autonomy and informed consent. In some cultures, a higher value may be placed on the harmonious functioning in the interlocking pattern of family relationships than on the autonomy of individual family members. For example, according to Okasha (2000) patients reared in some cultures may not wish to continue treatment with a physician who is not sensitive regarding the importance of involving the family directly in communications about the patient’s illness. The psychiatrist should diligently explore the role that cultural and family relationships play in the patient’s healthy mental functioning, and be guided primarily by the patient’s communications about their degree of comfort or conflict with these family relationships. Psychiatrists should be considerate and respectful of cultural differences between themselves and their patients, and be particularly cautious about interpreting those differences as a pathological process.

In addition to being mindful of cultural issues, indicated ways of encouraging autonomy include encouraging informed consent by outlining the potential benefits, risks, and alternatives for a proposed treatment approach; explaining the rationale for the treatment; and fostering the patient’s participation in the treatment process. Paradoxically, acutely suicidal patients often require the psychiatrist to assume temporary responsibility for their safety. In most cases this serves to augment the patient’s sense of autonomy through a coherent modeling process (Bratter 1975), since true independence is impossible without self-governance.
Clinical actions that may interfere with the patient’s autonomy include advice regarding non-urgent major life decisions; attempting to exert undue influence on issues unrelated to the patient’s health; reluctance to allow patients to terminate treatment; seeking gratification by exerting power over patients; and using power over patients as a form of retaliation.

Coherent and Non-Collusive Compensation
Although there are rewards to be obtained from working in an interesting and creative profession, this is best applied to one’s collective professional endeavors. With a specific patient, monetary compensation is the only gratification psychiatrists should realistically expect (Epstein and Simon 1990). When compensation is direct, there should be a set fee, and the patient should be responsible for the scheduled appointment time. When compensation is indirect or salaried, the psychiatrist must avoid colluding either with the patient against the party paying for the treatment, or with the third party against the patient (see the above Subsection “Avoiding Dual Relationships”). Whatever method is being used for paying for mental health treatment, a coherent and non-collusive arrangement imparts the message to the patient:

The doctor has needs of his/her own, but they are limited to a salary or fee. Aside from financial obligations, I don’t have to please, gratify, or nurture my doctor.

The practice of charging for missed appointments under the traditional fee for service paradigm is often misunderstood by patients, because their experience with physicians in other branches of medicine has usually been that they were charged on a fee-for-procedure basis, rather than fee-for-time. Charging for missed appointments is justifiable from an ethical standpoint as long as the rationale is clearly explained to the patient at the beginning of the treatment, and the patient agrees to it. In addition, no attempt should be made to hide the fact of billing for missed appointments from third party payers. Some states have an absolute prohibition against billing for missed appointments under entitlement programs such as Medicaid and Medicare (Epstein 1994, p 169). Within certain guidelines, it is permissible to bill the patient (but not Medicare) for missed appointments under the Medicare program (Epstein 1994, pp 169–170). Readers are cautioned that regulations regarding Medicaid and Medicare are subject to periodic legislative revisions, and may vary according to jurisdiction.

Generally risky compensation arrangements include working for a treatment organization one perceives to be financially exploitive; accepting inexpensive gifts from patients especially when such gifts are not part of a culturally expected mode of behavior; bartering goods or services in return for treatment; referring patients for treatments or procedures in which one has a proprietary financial interest; and neglecting the patient’s failure to adhere to the original agreement regarding payment of fees. Certain practices are absolutely contraindicated and likely to be destructive, including fraudulent billing; accepting expensive gifts; fee-splitting; colluding with the patient or third party; and use of financial insider information.

Confidentiality
It is essential that psychiatrists treat their patients’ communications as privileged. This means that patients alone retain the right to reveal information about themselves. The advent of managed care has raised even greater concern about the privacy of patients’ personal communications with their psychiatrists because of the potential for an increasing number of persons connected with the MCOs to have access to material from patients’ files. Psychiatrists should caution their patient about the potential limitations to confidentiality, and be prepared to explore the consequences of these exceptions. For example, if a patient is raising his/her mental health as an issue in litigation, some or all communications to a psychiatrist could be legally discoverable. Coherent boundaries with regard to confidentiality send the message to the patient:

My thoughts and feelings belong to me. The doctor does not treat them as if they belong to him/her.

Indicated means of preserving confidentiality include obtaining proper authorization from patients before releasing information; explaining the need for confidentiality with parents of children and adolescents; and involving all participants in family and group psychotherapy in agreements about confidentiality. Problematic activities that may endanger confidentiality include stray communications with concerned relatives of patients in individual psychotherapy where there is not a prior expectation on the patient’s part about discussions with relatives; discussion of privileged information with the psychiatrist’s own family members; releasing information about deceased patients; and failure to properly disguise case presentations.

Anonymity
Many psychiatrists associate the principle of relative anonymity with Freud’s advice to psychoanalysts (Freud 1912):

The doctor should be opaque to his patients and, like a mirror, should show them nothing but what is shown to him.

Freud argued that it was dangerous for psychoanalysts to expose their own mental problems or intimate life details in a spurious attempt to place themselves on an “equal footing” with patients (Freud 1912, pp 117–118). The merit of this recommendation extends beyond its origin in psychoanalytic technique to a fundamental boundary issue applicable to all forms of psychiatric treatment. It serves as a reminder to both patient and clinician of the professional purpose of the relationship. Avoiding unnecessary personal disclosure to patients protects both patient and practitioner from a reversal of roles—one of the critical themes recurring in boundary violations in general (Peterson 1992). Many patients experience excessive self-disclosure by the psychiatrist as seductive, and it has been frequently observed to be a precursor to subsequent sexual involvement (Schoener and Gonsiorek 1990, p 403). By maintaining a policy of relative anonymity, the patient receives the following message about the treatment:

This a place where I can bring my issues. The doctor doesn’t burden me with his/her stuff.
The psychiatrist should not construe the principle of anonymity to justify a demeanor that is aloof or distant. This can be very traumatic for some patients. To the contrary, when a patient insistently requests personal information about the psychiatrist that are not pertinent to the logistical and administrative aspects of treatment (e.g., whether the doctor planning to retire in the near future), the opportunity arises for the psychiatrist to become more engaged with the patient by explaining the reasons why personal revelations are likely to be damaging to the therapeutic process. It also presents an opening to ask the patient the reasons for their wanting to know the information, and enables one to explore with the patients their previous experiences of having emotionally important things hidden from them, or, conversely, the occurrence of developmentally inappropriate disclosures made by early caregivers.

Certain forms of self-disclosure are indicated in the course of work with psychiatric patients, including apprising patients regarding the clinician’s qualifications and treatment methods as part of informed consent; discussing reality factors about the psychiatrist’s health status or intentions regarding retirement that will impact on the patient’s treatment decisions; and using “reality checks” to help patients contain disturbed and frightening fantasies.

**Abstinence**

Abstinence means that psychiatrists should discourage direct forms of pleasure such as touching or sexuality in the course of their interactions with patients. In the therapeutic relationship, the patient’s ability to consent to sexual activity with the psychiatrist is vitiated by the knowledge the latter possesses over the patient, and by the power differential that vests the psychiatrist with special authority.

For patients, actual gratification from the psychiatrist is best confined to realistic goals for recovery and emotional growth. Psychiatrists should limit themselves to the pleasure of getting paid for a job well done, and for the opportunity to participate in an interesting and creative profession. Although steadfast application of this boundary can be quite frustrating for both doctor and patient, it pays excellent dividends in the long run by encouraging autonomy and a more mature way of dealing with impulses. The rule of abstinence as a therapeutic boundary has an analogous function to the incest taboo as a social organizer. In all known human cultures, the incest taboo has survival value because during childhood development, it serves to strengthen the sense of individuality and personal boundaries so necessary for growth, independence, and social responsibility (Parker 1976).

From a practical standpoint, psychiatrists can strengthen their patients’ boundaries in this regard by resisting behaviors such as physical touching, accepting gifts, socialization outside of treatment, and sexual involvement. The patient receives the following messages from a clinician who is able to properly adhere to this principle:

> The doctor is more interested in my health than his/her own gratification and doesn’t try to take possession of me. I am learning that I can have wishes that needn’t result in action.

There are occasions when psychiatrists are obligated to employ physical procedures such as taking blood pressures, checking for extrapyramidal symptoms, restraining dangerous patients, or administering electroconvulsive therapy (ECT). Indeed, clinical touching of patients is considered an integral part of the physician–patient relationship because of its important role in physical examination and therapeutic procedures. Even though psychiatrists are physicians, they are obligated to use much more restraint in this regard than is expected of colleagues in other branches of Medicine. It is probably too invasive for the same physician on a protracted basis, to simultaneously intrude both into the patient’s psychological and physical spaces.

Other risky forms of gratification include embracing or kissing patients; eating and drinking with patients; socializing with patients outside of the therapy setting; and failure to understand and resolve recurrent or obsessive sexual fantasies about a patient. Engaging in sexual behavior with current or former patients is contraindicated because it is almost invariably destructive, even though the damage may not be immediately manifested.

The APA (APA 1993) took a principled and unequivocal stand regarding sexual activity between psychiatrists and their current or former patients:

> Additionally, the inherent inequality in the doctor–patient relationship may lead to exploitation of the patient. Sexual activity with a current or former patient is unethical.

The APAs position is in agreement with the principles espoused in the Hippocratic oath, which clearly mandates that a physician approach a patient “for the benefit of the sick, and abstain from every voluntary act of mischief and corruption; and, further, from the seduction of females or males, of freemen and slaves.”

Despite the ancient basis of this proscription, and convincing evidence in our times of the damaging effects of sexual relationships between therapists and former patients (Epstein 1994, pp 218–220; Luepker 1990; Brown et al. 1992) some authors have raised legal and theoretical challenges to the permanent prohibition contained in the APA guidelines (Appelbaum and Jorgenson 1991). While refraining from calling for a repeal of APA’s ethical proscription against sex with former patients, Malmquist and Notman (2001) argued that legal misapplications of imprecise and unproven concepts of transference and countertransference have exposed therapists who enter post-termination sexual liaisons with their patients to inappropriate legal liability.

Research examining the causation and prevention of human error has provided neurocognitive evidence supporting the ancient wisdom of Hippocrates’ injunction. Skilled performance is subject to potentially calamitous error when experts fail to follow empirically derived safety guidelines, or lack an adequate knowledge base upon which to initiate critical interventions (Reason 1990). Skillful performance in conducting medical procedures is acquired from over-learned behavior that enables an expert to undertake complex cognitive and behavioral operations in a smooth and rapid fashion. Performance skills whose success depends on over-learned and automatic processes rely primarily on the procedural memory system (Cabeza and Nyberg 2000). The Hippocratic mandate of approaching the patient solely for their benefit and to avoid mischief, is a prime example of
an over-learned automatically embedded error protection message acquired through years of medical training. Anything that interferes with such an intensively elaborated internal safeguard endangers patients’ well-being.

Whether they realize it or not, psychiatrists who justify the permissibility of post-termination sexual relationships are sabotaging their own over-learned commitment to act primarily in their patient’s best interest, and are exposing their patient to a biased and error prone treatment. This self-permissive attitude would make a psychiatrist more prone to engage in seductive grooming of a patient during the treatment process in anticipation of termination. In addition, biased by this attitude, a psychiatrist is likely to avoid making any communication to the patient that would discourage a subsequent romantic post-termination liaison (Epstein 2002). While a psychiatrist might consciously deny that this attitude is a violation of the Hippocratic dictum, in actual cases where psychiatrists have engaged in post-termination sex with patients, their pre-termination subliminal thinking ran like this:

I’m treating this patient only for her/(his) benefit. Like Hippocrates, I will abstain from every voluntary act of mischief and corruption and further, from seduction. However after I cure this very attractive patient, I will keep his/her phone number and after a respectable period of time, it will be a different matter, and we will see what will happen.

Note that this reasoning represents a form of dissociative thinking based on a primitive wish for inappropriate gratification with a patient that magically disavows the connection between post-treatment behavior and pre-treatment reality. All psychiatric treatment is based on the assumption that a psychiatrist’s interventions by means of positive attitudes, words, deeds, and medical interventions will have a lasting beneficial effect on the patient after the treatment has ended. There is no realistic escape from the fact that the reverse is also true, namely that inappropriate attitudes, words, deeds, and interventions are likely to have a lasting harmful effect on the patient after the treatment has ended.

For the reasons outlined above, psychiatrists should adhere to the dictum of “once a patient, always a patient.” The vast majority of our patients suffer from chronic struggles. It is not uncommon for patients who have terminated from treatment to return to the same psychiatrist for further assistance, sometimes several decades later. Any attitude or behavior that could predispose the psychiatrist to ignore this clinical reality will increase the risk of serious harm to the patient and the treatment process.

Self-respect and Self-protection

It is essential that psychiatrists protect themselves from being exploited by patients. This principle is necessary to protect clinicians and patients alike. Many patients seeking treatment have endured abusive relationships in which being victimized became the price for maintaining human connectedness. For such patients, efforts to exploit the psychiatrist may be an action-question that inquires:

Must one of us be injured in order for us to have a close relationship?

By setting a proper role model for self-respect, and self-caretaking, the psychiatrist imparts the following message to the patient:

Relationships need not be structured on the basis that one or both parties must be exploited. If I as the doctor allow you to hurt me, I am setting a poor role model.

Psychiatrists should attempt to discuss the meaning of any exploitive behavior on the patient’s part as soon as possible. With unstable or impulsive patients who are prone to acting out, confrontation should be timed to maximize safety. For example, it would be more prudent to interpret the manipulative aspects of a patient’s suicidal behavior after the patient is admitted to a hospital. If a patient makes a sudden physical overture such as attempting a sexually provocative embrace, it must be dealt with the same urgency as a physical assault. The psychiatrist should inform the patient that such behavior is inconsistent with coherent treatment (Epstein 1994, pp 228–231; 58). It is generally risky to allow repeated exceptions such as last-minute prolongation of sessions or repeated lateness in paying fees; excessive intrusion into the psychiatrist’s personal space in the form of regular and frequent late night phone calls or taking items from the office.

Certain psychiatrists find themselves avoiding confrontation with an exploitive patient out of fear of the latter’s narcissistic rage. This is an indication of an escalating situation that may lead to further boundary violations either by the patient or the psychiatrist. A useful explanation of this behavior is provided in Gabbard’s (1994) description of a sub-group of clinicians who become sexually involved with patients as part of a self-defeating pattern of behavior he termed “masochistic surrender.” These practitioners are unable to defend against being tormented by certain highly demanding patients. They succumb to the patient’s importunings, sometimes while in a dissociated state, even though they may know their behavior is wrong. Gabbard (1994) argued that the aberrant behavior of these clinicians is rooted in an impaired ability to cope with their own aggressive feelings, resulting in their feeling that it would be sadistic to set limits on the patient.

Summary

The ethical and boundary issues discussed in this chapter were designed to stimulate a better understanding of an extremely thorny topic, rather than to provide an exhaustive compendium.

Table 5–7 summarizes selected indicators of potential boundary violations, along with remedial responses. These responses might employ the following strategies. A burgeoning literature regarding the psychological characteristics of clinicians who have problems with maintaining proper boundaries (Epstein 1994, Gutheil and Gabbard, 1993, Epstein and Simon 1990, Schoener and Gonsiorek 1990, Gabbard 1994, Twemlow and Gabbard 1989, Gabbard 1991, Geis et al. 1985) provides useful guidance in this regard. The difficulties psychiatrists may encounter in keeping boundaries derive from many sources. In the past, professional training programs have not addressed this issue systematically. Recent proposals to bolster the study of ethics and boundaries in medical school and residency programs (Roman and Kay 1997, Kay and Roman 1999), will help to remediate this problem. It behooves psychiatrists to determine whether they have suffered deficiencies in training...
Indicators of Potential Boundary Violations with Suggested Remedial Responses

Introduction
Our society values individual freedom, autonomy, and privacy. Sometimes a patient’s individual interests or stated desires may be at odds with those of society. Questions such as whether to pursue involuntary hospitalization for a severely ill patient, how to manage a patient who refuses appropriate medical treatment, or whether to divulge information about a potentially dangerous patient to police may arise in these circumstances. Mental health law encompasses the efforts of courts, legislatures, and regulatory agencies to resolve the questions and conflicts that arise between patients, clinicians, and the state (i.e., society). Since issues pertaining to legal aspects of patient care arise for all clinicians, an understanding of the clinical-legal tensions that arise in psychiatry and of the legal regulations governing the field is necessary for effective practice.

The subspecialty of forensic psychiatry focuses specifically on issues at the medico-legal interface. However, the role of the forensic psychiatrist differs from that of the practicing clinician in several key aspects. In most circumstances, the forensic psychiatrist owes his agency to—or works for—a third party (e.g., the court system) rather than a patient. Most often, the purpose of the forensic psychiatric evaluation is to assess for the presence of a condition or impairment and to aid third-party decision makers in an adversarial or adjudicative proceedings (e.g., in determining competence, reaching a verdict, or in assigning a disability rating) rather than to provide treatment. Because agency and purpose in forensic evaluations differ, the degree of diagnostic certainty required for such assessments may also differ. The forensic evaluator, as compared to a clinician in a traditional doctor–patient relationship, may require a greater reliance on objective findings in an effort to establish “historical truth” as the basis for action. The clinician may be more inclined to base clinical decisions on the “narrative truth” elicited from the subjective reports of a patient’s experiences (Cohen 2003).

This chapter will provide an overview and organizational framework for understanding the law as it is applied to the practice of clinical psychiatry. For the interested clinician, a number of textbooks provide more detailed discussions of the practice of forensic psychiatry (Gutheil and Appelbaum 2000, Lande and Armitage 1997, Rosner 2003, Simon and Gold 2004).

Categories of Legal Issues in Psychiatry
Table 6–1 outlines categories into which legal issues in psychiatric practice may be divided. Legal issues surrounding mental illness and treatment may be broadly divided into two groups: civil issues and criminal issues. Civil issues may be further subdivided into patient’s rights issues including involuntary hospitalization or treatment refusal and doctor–patient issues such as patient–therapist privilege, confidentiality and malpractice. Criminal issues tend to focus on competency to stand trial and criminal responsibility (i.e., whether a person accused of a crime should be held responsible and punished or should be found not guilty by reason in insanity). Behaviors or psychiatric conditions of persons alleging a crime or having been victimized may also be matters for the court’s consideration. Other issues such as the degree to which psychiatric illness may potentially contribute to repeat offenses or alter punishment determination may also be considered criminal issues.

Civil Issues: Patient’s Rights

Involuntary Hospitalization

In the United States, an individual may be involuntarily hospitalized for psychiatric reasons only if certain legal criteria are met. Therefore, clinicians do not actually commit patients. The psychiatrist often initiates commitment proceedings by certifying that a mental illness requiring hospitalization exists and that a patient is refusing voluntary hospitalization. A legal decision-making body is thereby petitioned to order hospitalization. The decision as to whether a patient is actually involuntarily hospitalized ultimately rests with the courts—or in some states quasijudicial boards. Although the statutory language for involuntary hospitalization (civil commitment) varies from state to state, three principles serve as the basis for all commitment laws. The individual must be

- mentally ill, and
- dangerous to self or others, or
- unable to provide for his or her own basic needs (i.e., “gravely disabled”).

In most statutes, the term mentally ill is not clearly defined but requires the petitioner (e.g., the psychiatrist) to state the psychiatric problem necessitating hospitalization. In some states, additional criteria such as an overt act of violence toward self or others or damage to property within a specified period of time, or the absence of available less restrictive treatment alternatives, must also be established before an individual is hospitalized against his or her expressed desires. Most states allow for a period ranging from 1 to 20 days of emergency hospitalization for the purposes of providing immediate crisis intervention and completing a more detailed evaluation. All states require periodic reassessment of the need for continued involuntary hospitalization (Guthheil and Appelbaum 2000).

When persons are involuntarily hospitalized, they generally maintain their rights to manage their own financial matters, to communicate with others via phone or mail, and to receive personal visitors. They also have rights to privacy including space to secure valuables, private bathing and toilet facilities, and personal space. These rights are typically statutorily quantified. In most states, the right of psychiatric inpatients (including those involuntarily committed) to refuse therapy and/or medication is also preserved. Involuntarily hospitalized patients require a separate judicial proceeding to establish incompetence to manage finances before a guardian can be appointed or to establish incompetence to make medical decisions before involuntary medications may be ordered.

Patients’ rights in hospital settings may be restricted by the clinical judgment of treating professionals in consideration of both the patient’s interests and the rights and safety of other persons within the hospital. Involuntary hospitalization, even when accomplished entirely in the patient’s best interests, represents an extreme curtailment of civil liberty. Disputes over violations of patient’s rights in such situations are inevitable. In many jurisdictions, a civil rights officer or ombudsman is mandated to assist in resolving these disputes. Occasionally, patients or their ombudsmen allege that a psychiatrist has failed to act in good faith or adhere to statutory requirements in petitioning for commitment. Lawsuits may be brought under the theories of wrongful imprisonment, malicious prosecution, or abuse of authority (Simon 2002). Fortunately, most states grant immunity from liability for psychiatrists exercising reasonable professional judgment when initiating commitment. However, a psychiatrist may be successfully sued if evidence exists of willful or blatant failure to adhere to commitment procedures. Psychiatrists must therefore be aware of specific regulatory guidance surrounding commitment wherever they practice.

The Psychiatrist’s Role in Hospitalization Decisions

In most cases, the decision for psychiatric hospitalization represents the culmination of a collaborative dialogue between the clinician and his patient. The decision is made by the patient after a thorough discussion of the reasons for the physician’s recommendation for hospitalization, the risks, benefits, and alternatives to hospital treatment. This dialogue also allows for the clinician’s assessment of the patient’s ability to understand the ideas discussed, manipulate information, and come to a rational decision. Thus, most hospitalizations occur with the informed consent of a patient capable of making treatment decisions (including whether or not to be admitted to the hospital). The idea that physicians must obtain and document informed consent before initiating any form of treatment is a universally recognized principle of medical practice and failure to do so frequently underlies malpractice claims (see below).

In situations where involuntary hospitalization is sought, it is impossible to obtain informed consent. Typically, an individual is brought to emergency clinical attention by a law enforcement official because the individual was acting in a bizarre manner, or was demonstrating or threatening behavior dangerous to self or others. The psychiatrist is asked to assess the individual and make a decision about disposition in situations when an individual does not demonstrate a capacity to rationally discuss psychiatric treatment options or hospitalization. If the psychiatrist believes the person to be mentally ill, dangerous, and/or gravely disabled, the appropriate legal body (e.g., the hospitalization magistrate court) is provided with appropriate documentation, and a commitment order is sought. Generally, reasonable clinical judgment dictates erring on the side of safety rather than allowing a potentially dangerous individual to leave the emergency room. Similarly, when a voluntarily admitted patient requests hospital discharge but is believed to present an ongoing danger to self or others, a court order for continued (involuntary) hospitalization may also be sought. Most states require that a clinician other than the primary treatment provider must certify mental illness, dangerousness, and/or grave disability under these circumstances.

During the deinstitutionalization movement of the 1970s, the courts increasingly took over the authority to determine whether commitment was legally appropriate. The majority of states began to adopt outpatient commitment statutes under which persons could be required by the courts to receive treatment in community settings. Some critics have argued that dangerousness criteria required for commitment, if met, cannot be satisfied by outpatient care and also that relaxation of this requirement may allow
for abusive violation of civil liberties (Mulvey et al. 1987). Others have argued that without sufficient community resources, and in the context of a preserved right to refuse specific treatment, outpatient commitment is ineffective in establishing safety to the individual or community (Munetz et al. 2000, Stein and Diamond 2000). As states continue to adopt and refine their outpatient commitment regulations, psychiatrists must pay increased attention to their potential roles in determining which patients may be appropriate for outpatient commitment and to the challenges associated with caring for patients in this status and in such settings.

Competency and Treatment Refusal

As noted above, for most patients including those hospitalized involuntarily, the right to refuse specific treatment is preserved. This is not the case for persons legally declared incompetent to make medical treatment decisions. All physicians routinely assess their patients’ abilities to make medical decisions as they obtain informed consent for treatment or procedures. Typically, caregivers assess their patients’ abilities to make treatment decisions implicitly rather than through an explicit process. Psychiatric consultation tends to be requested only when questions arise surrounding a patient’s decision making such as when a patient refuses an important diagnostic or therapeutic procedure, or refuses physician-recommended medication(s). In these situations, a psychiatrist may be asked to determine whether the patient is competent to make treatment decisions.

As with involuntary hospitalization, “competency” is a legal determination, rather than a medical one. All persons are presumed competent unless they have been explicitly declared legally incompetent by the appropriate court. This rule holds for even the most severely psychotic or demented patients. While a determination of incompetence is a legal one, in practice the judicial system relies heavily on medical expert testimony in making such determinations. Therefore, psychiatrists should be comfortable with processes used to assess the extent to which a patient’s capacity to make a particular decision may be impaired. Capacity—or functional impairment—is a clinical rather than legal determination.

Decision-making capacity and competence are task specific. Patients may be competent (e.g., demonstrate the capacity) to make some medical decisions but not others depending on the complexity and consequences of the medical decision and the complexity of the medical information the patient must understand. Since there is not a single legal standard for competency, appropriate criteria for assessing decision-making capacity may vary from jurisdiction to jurisdiction. Beyond clinical judgment about the complexity of the medical decision and relevant clinical information, basic principles underlying legal determinations of medical competency have been identified by Grisso and Appelbaum (1998). These concepts provide a framework for the clinical assessment of medical-decision-making capacity. They are summarized in Table 6–2.

All courts have accepted the notion that patients who are unable to communicate a choice are not competent to make medical decisions. Therefore, a comatose patient, or a psychotically paranoid patient refusing to speak to all clinicians, would be declared incompetent to make treatment decisions. More than merely communicating a decision, most courts have determined that a patient’s stated decision must be sufficiently stable to be considered evidence of competence. A patient’s decisions need not be fixed (e.g., a patient may change his mind upon further consideration). However, inconsistent responses of an amnestic or severely demented patient responding to a repeated question without consideration of the facts recently presented or who appears to be forgetting his previous responses would not be considered evidence of competence.

The degree to which a patient understands the relevant facts may be discerned from the questions he or she asks during the informed consent process. The patient’s ability to paraphrase information presented or to ask questions about potential benefits, risks, and side effects that are reasonable derivations from the information provided by the clinician suggest understanding. A determination that a patient does not understand relevant information requires more clinical judgment than a determination of the patient’s ability to communicate a choice. However, the idea that a patient cannot give informed consent if he does not understand the facts presented is also widely accepted by the courts.

Determining the ability of a patient to appreciate how the facts apply to his particular case and the ability to rationally manipulate data require an even higher level of clinical judgment. These capacities relate to insight (or the extent to which insight is diminished as a result of psychiatric illness) and to higher cognitive processes such as prioritizing and balancing probabilities. A severely depressed, newly diagnosed HIV patient may be able to understand that antiretroviral therapies are life prolonging. He may even understand that the vast majority of persons will respond. But he may, as a result of depression-related hopelessness, believe that the medications will not be able to help him. An assessment of the facts of treatment distorted by depression might also impair the patient’s ability to weigh the benefits of treatment over the risks of side effects.

While most courts recognize understanding of the relevant facts and ability to communicate a choice as sufficient standards for competence, psychiatrists should, in their assessments of decision-making capacity, comment on the patient’s abilities to apply the relevant facts to his or her particular case and the ability to rationally manipulate data. The psychiatrist should focus on signs that demonstrate that the patient is (or is not) applying the facts to his or her own situation (e.g., weighing the expected side effects of a treatment in association with his or her own social and occupational priorities), considering and balancing alternatives, and prioritizing. The clinician may not base determination on the extent the patient’s ultimate decision corresponds to clinical recommendations.

Except in emergencies, patients lacking medical-decision-making capacity need an authorized representative

or court-appointed guardian to make treatment decisions. The time and cost of formal legal proceedings for an adjudication of incompetence may be daunting for many families, and may delay appropriate treatment. Some states allow for legally authorized proxy consent of the next of kin when a patient is thought to be incompetent. All states allow for the establishment of a durable power of attorney, which allows for patients’ next of kin to consent when a patient becomes incompetent. Some states have passed health-care proxy laws creating documents similar to durable power of attorneys but limited to health-care decisions. Since consent options vary from state to state, psychiatrists should be aware of the options available to patients and their families in the jurisdictions they reside (see Table 6–3).

**Civil Issues: Doctor–Patient Relationship**

**Informed Consent**

The legal doctrine of informed consent requires that physicians obtain informed consent before initiating any treatment or procedure. According to this doctrine, three elements must be satisfied for a patient’s consent to be considered valid. Consent must be

- competent
- informed, and
- voluntary.

By requiring patients to demonstrate the capacity to make medical decisions and physicians to fully disclose information about likely and severe risks or side effects, benefits, and alternatives and to answer patient questions, the informed consent doctrine facilitates patients becoming partners in medical treatment decisions. That consent is voluntary means that a physician may not manipulate the patient by introducing information that might undermine the patient’s ability to understand potential outcomes (e.g., by exaggerating potential outcomes of the offered treatment, risks of not accepting the treatment, or declining provision of further care if a specific treatment is refused).

As with medication therapies, informed consent is required for electroconvulsive therapy (ECT). Many states require signed, written consent forms for this treatment. Informed consent must include a discussion of the risks of anesthesia as well as the ECT itself (to include memory loss). Most states require that consent must be obtained from the courts when competency is in question, and in Illinois, the courts have specifically ruled that guardians cannot consent to ECT for their wards and that parents may not consent for their adolescent children without judicial review (In re Brennan 1996, Matter of A.M.P. 1999).

The ethical guidelines of both the American Psychiatric Association and American Psychological Association require that informed consent be obtained prior to the initiation of psychotherapy (American Psychological Association 2002, American Psychiatric Association 1998). The extent to which it is obtained and documented in clinical practice has not been well studied. This practice is made more challenging by uncertainties about the relative risks and benefits of specific psychotherapies for various and at times comorbid psychiatric diagnoses. The courts have recently awarded considerable damages in “recovered memory” litigation (Beahrs and Gutheil 2001) related to the potential consequences of recollection of childhood events of questionable veracity. In the case of Oscheroff v. Chestnut Lodge, the plaintiff sued after spending a year in a hospital receiving only psychoanalytic treatment for severe depression. The case was settled out of court, leaving open the question of psychotherapist liability for failure to disclose the alternative forms of psychotherapy or the potential use of medications (Malcolm 1986).

There are several exceptions to the requirement of informed consent. In emergency situations where the patient experiences an acute threat to life requiring immediate medical attention, consent is implied when the patient is unable to communicate a choice (e.g., unconscious). Circumstances and options when the patient is incompetent are addressed elsewhere in this chapter. A competent patient may also decline being informed of all facts relating to a medical decision (waiver) and a physician may choose to withhold full disclosure if disclosure would seriously worsen a patient’s condition or impede rational decision making (therapeutic privilege). In situations where a psychiatrist asserts an exception to informed consent, his reasoning should be clearly documented in the medical record.

**Consent to the Treatment of Minors**

Historically, the law has considered minors—children under the age of 18—incompetent to make medical decisions. In the last half-century various states have authorized children aged 13 through 18 varying degrees of autonomy in some medical decision making. More than one third of the states (and the District of Columbia) grant some minors the authority to consent to outpatient mental health services. Most of these states impose age restrictions and preclude medication use for minors who obtain services without parental notification or consent. The majority of states also allow minors to obtain counseling services for substance-use related problems without parental consent. Emergency evaluation of minor students by psychiatrists working in schools is permissible in most states. However, parental consent for initiating and ongoing treatment is generally required. When parents are divorced or separated, informed consent for treatment must be obtained from the parent with legal custody. Emancipated minors—those legally determined to be capable of living on their own and managing their own affairs—are considered competent to make their own medical decisions. Some states recognize “mature minors” as those capable of appreciating the nature and consequences of medical treatment without requiring emancipated status. Psychiatrists evaluating or treating minors
must be knowledgeable of the specific laws regarding consent to the treatment of minors in the states in which they practice. Exceptions to the doctrine of parental consent or parental notification exist in most jurisdictions for mental health counseling, substance abuse counseling, and sexually transmitted disease (STD) testing. Some states waive parental consent for the treatment of STDs and more than half allow for contraceptive services, prenatal and delivery services without parental consent (Schlam and Wood 2000). While psychiatrists do not provide all of these services, knowledge of the state regulations in these areas may facilitate initial psychiatric assessment and psychotherapeutic intervention in minors seeking assistance from mental health professionals surrounding these issues.

Confidentiality and Privilege

One hallmark of the doctor–patient relationship is confidentiality—the obligation of a physician to keep patient communications spoken or written in confidence undisclosed to outside parties without authorization. The ethical codes of various medical and mental health professional organizations (including the American Medical Association, the American Psychiatric Association, and the American Psychological Association) all recognize this patient right and expectation in their ethical codes. Moreover, all 50 states and the District of Columbia have included confidentiality provisions in professional licensure laws or other statutes. Confidentiality is considered an element of the fundamental right to privacy, derived from various guarantees in the Constitution.

The psychiatrist has a duty to safeguard patients’ disclosures once the doctor–patient relationship has been established. However, the obligation is not absolute. There are circumstances where breaching confidentiality is both ethically permissible and legally required (see Table 6-4). Patients may waive confidentiality. Such waivers may be necessary for participation in managed care settings. Patients routinely authorize disclosure to employers or insurance companies to obtain benefits. All states and the District of Columbia require that physicians report certain infectious diseases, child abuse or suspicion of child abuse. These reports may necessitate a breach of confidentiality. Some states have similar reporting requirements for elder abuse. Most states either require or permit physician disclosure of patient confidences when these relate to behavior potentially harmful to a third party. The laws detailing specific situations where a psychiatrist may have either a duty to warn or a duty to protect, as articulated in the 1976 California Supreme Court’s Tarasoff decisions vary from state to state (Tarasoff v. Regents of the University of California 1976). The degree of discretion a psychiatrist has in discharging these so-called Tarasoff duties (either through warning a potential victim, by notifying the police, or other means) varies by jurisdiction. Some states require that a physician take steps to warn a potential victim, others to notify police, or to secure hospitalization of the potentially dangerous patient. Other states permit a physician to exercise clinical judgment as to which if any of these steps are taken (Kachigian and Felthous 2004, Herbert et al. 2002).

Testimonial privilege is sometimes confused with confidentiality. As noted above, confidentiality is an ethical obligation of the physician, which is abrogated in certain situations. Privilege is a statutorily defined rule of evidence that permits the holder of the privilege (the patient or his representative) to prevent the holder of confidential information from disclosing this information in a legal or administrative proceeding. Confidentiality and privilege are compared and contrasted in Table 6-5. While there is no specific constitutional “right to privacy” the language of the 1st, 4th, 5th, and 14th amendments have been interpreted by the courts to support the existence of a constitutionally derived right to privacy. It is noteworthy that while only 42 states recognize a specific physician–patient privilege, all 50 recognize a specific patient–psychotherapist privilege. A psychiatrist is considered a psychotherapist in all of these statutes.

Malpractice

Psychiatric malpractice occurs when negligence in the conduct of one’s professional duties results in injury to a patient. Negligence may result by acts of commission (e.g., doing something one should not) or acts of omission (e.g., failing to do something one should) on the part of a psychiatrist with a duty to care for a patient. Tort law—the body of law pertaining to noncriminal wrongdoing—specifies procedures and standards for plaintiffs (patients or their families) seeking remedy for physician negligence.

The exact language of the legal standard of care to which psychiatrists are held varies from state to state but generally requires that a psychiatrist must exercise the “the care and skill customarily exercised by a similarly prudent (or qualified) psychiatrist”. To prove malpractice, the plaintiff must establish by a preponderance of evidence that (1) a doctor–patient relationship existed that created a duty of care, (2) the doctor’s care was a deviation from the legal standard, (3) that the patient was damaged, and (4) that the
deprivation *directly caused* the damage. Direct causation is the phrase articulating the idea that damage would not have occurred but for the action (or omission) of the psychiatrist. These four elements are often referred to as the “four D’s” of medical malpractice (Table 6–6). In the courtroom, experts (often forensic psychiatrists) representing the psychiatrist and the plaintiff testify as to whether the plaintiff’s psychiatrist deviated from the standard of care based on a discussion of relevant textbooks and journals, practice guidelines, and the ethical and practices guidance of professional organizations (Simon 2005).

### Table 6–6  The “Four D’s” of Medical Malpractice

In civil liability cases, the plaintiff need only establish the “four D’s” of malpractice by a preponderance of evidence, meaning that it is “more likely than not” that duty, deviation, damage, and direct causation occurred in the specific case. This level of proof is much less rigorous than either the “clear and convincing evidence” standard used in commitment proceedings (discussed above) or the “beyond a reasonable doubt” standard of criminal trials (see Table 6–7). However, unless each of the four elements is established as being more likely than not, there is no physician liability. For example, if a patient is harmed as a result of a medication side effect, but a psychiatrist exercises and documents appropriate care in making a diagnosis, considering treatment alternatives, obtaining informed consent, and monitoring treatment then malpractice has not occurred.

Although it is estimated that 50–65% of all physicians will experience at least one malpractice lawsuit during their careers, psychiatrists tend to be sued less often than other physicians. One reason is that by virtue of the treatments they provide psychiatrists are less likely to kill or maim a patient. Also, psychiatric care may focus more on the development of the doctor–patient relationship and often on the development of long-term care relationships than other specialties. Both patients and families view such relationships as demonstrative of the concerned and dedicated care provider doing his or her best for the patient. Lawsuits tend to occur when bad outcomes are associated with bad feelings about the physician on the part of the plaintiff.

Patient suicide is one of the most frequent outcomes associated with psychiatrist lawsuits. Suicides occurring in hospitalized patients often result in litigation, since one purpose of hospitalization is to provide close monitoring and a safe environment for patients with suicidal ideation. In a hospital environment, psychiatrists are assumed to have greater control of their patients’ actions. In such situations, malpractice is more likely to be established when physicians, nurses, or other medical staff members fail to adhere to hospital or Joint Commission on Accreditation of Health Care Organizations policies and regulations regarding the monitoring of suicidal patients.

“No-suicide contracts” have been used by clinicians under the mistaken belief that these will protect them from liability. There is no evidence that a “no-suicide contract” reduces suicide, litigation, or adverse legal outcomes (Kroll 2000, Simon 1999a). Such contracts may create a barrier to patient communication or to the development of therapeutic alliance and may inappropriately diminish vigilance for suicidal potential (Miller et al. 1998). These contracts cannot be considered an adequate measure for protecting patients or physicians.

The courts have recognized that current medical knowledge does not fully allow for the prediction of suicidal behavior—particularly in less restrictive (e.g., outpatient) settings. Consequently, outpatient psychiatrists are somewhat less likely to be sued when patients commit suicide. However, routinely assessing for risk of suicide, monitoring changes in risk, and providing treatment informed by ongoing risk assessment are considered part of the standard of psychiatric care in both inpatient and outpatient settings (Simon 1999a). The courts have generally held that suicide should be prevented if it is *reasonably foreseeable*, suggesting that a psychiatric risk assessment should be reasonable (e.g., include an examination for known risk factors such as history of suicide attempts, depression, anxiety, psychosis, recent socioeconomic or interpersonal loss, possession of firearms and substance abuse). Management plans should also be altered to reflect changing risk factors. Psychiatrists should carefully document and periodically update suicide risk assessment in their patients as well as interventions aimed at mitigating the risk.

**Clinical Vignette 1**

A businessman refers his 23-year-old stepdaughter to a psychiatrist, explaining: “I told her she could only come to work in my office if she got her act together, stopped partying so much, stopped acting so down and out every time things didn’t go her way, and acted more responsibly.” At the initial evaluation, the woman relates a lengthy history of low self-esteem, intermittent episodes of depression accompanied by neurovegetative symptoms, a history of deliberate self-injurious cutting behaviors when particularly feeling “overwhelmed by my life,” and of suicide attempts (via combinations of medication and alcohol overdoses), and related psychiatric hospitalizations. She notes that she has neither attempted suicide, nor been hospitalized since her mother remarried 8 months ago.

At the time of the evaluation, she denies depressed mood or neurovegetative symptoms of depression explaining, “the only good thing my last doctor did was start me..."
Liability for Supervising Other Professionals

Physicians may interact with a variety of other mental health professionals in providing care for a given patient and may have different levels of responsibility for the care provided by others. In broad terms, a psychiatrist may supervise other clinicians, may collaborate with others in treatment, or he may be asked by another professional to provide consultation.

When a psychiatrist supervises another therapist, the supervisor gives active guidance and professional direction and retains responsibility for patient care. The legal doctrine of *respondeat superior*—"let the master answer for the deeds of his servant"—provides the basis for the assumption of liability by the supervising psychiatrist in malpractice cases involving the care provided by those whom he supervises. When a psychiatrist provides consultation, guidance provided may be accepted or declined by the professional seeking consultation. Therefore, the consulting psychiatrist is not considered to have assumed responsibility for the patient's care.

Frequently, the relationship between the psychiatrist and nonphysician therapist takes the form of collaboration. Here, the responsibility for patient care is shared between the two clinicians in accordance with the professional qualifications and limitations of their respective professions. It is important to recognize the degree of ongoing communication between collaborators necessary to provide most effective care and continued clarity amongst patient and collaborators regarding the boundaries of responsibility. The American Psychiatric Association’s professional guidelines require that patients be fully informed of the nature of the relationship between the psychiatrist and others interacting in care and that the responsibilities of psychiatrist and other therapists be delineated to the patient. The guidelines indicate that both the psychiatrist and collaborating therapist are responsible for periodic reassessment of the appropriateness of the continued collaboration for patient care, and for notifying the patient if the collaboration is terminated (American Psychiatric Association 1980).

Physician–Patient Boundary Violations

The professional ethical code of the American Psychiatric Association explicitly states that a psychiatrist should not have sexual contact with current or former patients (American Psychiatric Association 1998). Accordingly, sexual activity between a psychiatrist and a patient or former patient has become a relatively common cause for malpractice litigation. In addition to monetary damages, psychiatrists face reprimand or expulsion from professional organizations and suspension or revocation of their medical license for such deviations from the standard of care. Many states have adopted statutes specifically related to patient–therapist sexual misconduct, facilitating either criminal prosecution or civil litigation (Simon 1999b). Other malpractice claims experienced by psychiatrists may involve incorrect treatment (e.g., failure to appropriately evaluate, diagnose, prescribe treatment, monitor or supervise care), improper commitment, breach of confidentiality, slander, and libel. Such claims (e.g., incorrect treatment) may arise in the context of physician–patient boundary violations or under unrelated circumstances.

Disability and Fitness Evaluations

In conducting complete psychiatric evaluations for the purpose of treatment, clinicians must evaluate the degree of
distress and/or social or occupational impairment attributable to mental disorder symptoms, in order to determine the severity of illness, and to establish a baseline for monitoring the utility of clinical interventions. In contrast, when conducting evaluations for workers compensation and the Social Security Administration, psychiatrists are called upon to determine psychiatric disability. Federal statutes define impairment as essentially any physical or mental disorder, defect, illness, loss or condition affecting organ systems (including the nervous system). However, disability is defined as the extent to which impairment limits or precludes a person’s ability to meet important psychosocial or occupational demands. Specifically, disability determination requires

1. a physical or mental impairment that substantially limits one or more of the major life activities of such individual,
2. a record of such an impairment, or
3. being regarded as having such an impairment

Workers compensation, paid for disability occurring in the workplace, is a remedy based on the worker’s prior salary and degree and duration of disability. As an alternative to litigation, states have developed mandatory insurance programs into which employers pay to provide coverage for workplace-related injuries. States vary in their implementation of workers compensation programs. In most there are no awards for pain and suffering (as might occur in civil litigation) but compensation is provided for physical trauma causing mental injury, mental injury causing physical deficits, and mental stress causing mental deficits. Social Security disability—for persons who contribute to the fund while working—was established in 1956. Supplemental Security Income was established as a federal matching payment for state benefit programs in 1972.

In litigation and in determination of medical disability benefits, it is the degree of disability (not the specific diagnosis or mere presence of impairment as defined above) that determines the amount of damages or monetary award. In the military active duty and Veteran’s Administration Medical Care systems, clinicians must often make assessments of disability and determine whether disability is related to military service. Various regulations guide the conduct of disability examinations for military members (Ritchie et al. 2006). In workers compensation and tort actions, causation is a necessary factor in the determination of monetary award. Social Security disability focuses more precisely on the diagnostic criteria of the Diagnostic and Statistical Manual of Mental Disorders without concern for causation. The Social Security Disability Reform Act of 1984 mandates medical improvement prior to termination of payments so documentation of treatment and course of symptoms is important in ongoing Social Security disability evaluations. The American Medical Association has published guidelines for the conduct of disability determinations, which parallel processes recommended by the Social Security Administration (American Medical Association 2004).

While treating physicians may be placed in the role of completing disability evaluations, they must be conducted in the context of other evaluations completed at the request of third parties. The physician must strive for objective determination of degree of impairment based on complete review of relevant medical records and other collateral information as well as specific reports from the patient quantifying the degree to which symptoms impede work or other life demands. Adjudicators of disability benefit from specific examples of barriers to work function created by psychiatric conditions. Examples might include avoidance of occupationally required situations that trigger reexperiencing phenomena and anxiety in persons with posttraumatic stress disorder.

In other situations, an individual may wish to maintain employment but may claim a need for accommodations under the provisions of the Americans with Disabilities Act or an employer or licensing board may question whether a person is able to work safely after accommodations are made. Psychiatrists are often asked to provide such input for police, fire, and rescue workers, and also for other physicians (McNaught and Schofield 1998, Rostow and Davis 2004). These evaluations are often called “fitness evaluations, return-to-work evaluations,” or “fitness for duty evaluations.” While patients and employers may request such evaluations from treating physicians (out of convenience or a belief that the treating physician may know best the patient’s degree of impairment) it may be difficult or inappropriate for clinicians to shift from therapist to disability evaluator. The differences in purpose, agency, and degree of medical certainty required in these different roles may warrant an independent medical examination conducted by a nontreating physician (American Academy of Psychiatry and the Law 2005, Simon and Wettstein 1997). Any disability or fitness for duty evaluation should be performed in the context of a specific question or questions (e.g., are there occupation-specific requirements and work environments precluded by impairment?), and include comprehensive medical and psychiatric evaluation and mental status evaluation, review of medical records, and collateral information from third parties such coworkers and employers (Anfang and Wall 2006).

Criminal Issues: Competency and Insanity

In contrast to the civil issues outlined above, practicing psychiatrists interact much less frequently with the criminal law system. In the tradition of common law and in subsequent case law and statutes, the basic elements of any crime are (1) commission of the criminal act itself termed actus reus or “guilty act” and (2) the mental level of intent or desire to commit the criminal act, termed mens rea, or “guilty mind.” In criminal proceedings the state (or government) must prove, by the most rigorous “beyond a reasonable doubt” level, that the defendant committed the criminal act with the requisite mental intent to do so in order to convict a person of a crime. Therefore a person’s mental state at the time of an alleged offense may play a critical role in determining whether he or she is found guilty or acquitted, sentenced to prison or hospitalized. The US Supreme Court has also established that before any defendant can be prosecuted he must understand the charges against him and must have sufficient mental capacity to assist counsel with the defense. While clinical psychiatric practice allows for varying degrees of diagnostic uncertainty, a variety of treatment options, and flexibility in determining care plans, the courts have...
adopted much more stringent criteria for determining whether mental state precludes prosecution or should be grounds for acquittal. Because of the societal value placed on civil liberty, the courts have held that safeguards such as the high standard of proof of guilt and more precise determinations of mental state are necessary in decisions that may result in the most severe curtailments of liberty such as imprisonment or execution.

**Competency to Stand Trial**

In a 1960 decision, the US Supreme Court established the standard for competency to stand trial in criminal proceedings. The court noted that “the test must be whether he (the defendant) has sufficient present ability to consult his lawyer with a reasonable degree of rational understanding—and whether he has a rational as well as factual understanding of the proceedings against him” (Dusky v. United States 1960). The ruling articulated the idea that competency refers to a defendant’s current mental capacity (e.g., at the time of the court proceeding rather than at the time of the alleged offense). Consequently, a defendant’s competency may be called into question at any point during criminal proceedings if mental capacity deteriorates. Subsequent court decisions have concluded that this standard applies not only to the process of standing trial, but also to decisions such as waiving the right to counsel, or to entering a plea of guilt or innocence (Godinez v. Moran 1993). The lack of explicit quantification of the terms sufficient or reasonable degree within this standard allows for considerable range of interpretation of this standard, and the courts rely on the input of mental health experts in making such determinations.

The determination of competency (or incompetence) to stand trial does not hinge on a specific psychiatric diagnosis or even the presence of a psychiatric diagnosis. Rather, it is based on assessment of the defendant’s capacity to understand criminal proceedings. Questions or checklists identifying the defendant’s understanding of the roles and functions of witnesses, prosecuting attorneys, judge and jury, knowledge of potential outcomes (e.g., guilty vs. not guilty, potential punishments), defendant rights with regard to counsel, testifying and hearing the testimony of others against him, and the role defense counsel and his interaction with defense counsel are of practical importance in clinical assessment (Grisso 1986). The Supreme Court has determined that incompetent persons may not be held indefinitely merely for the purpose of restoring competence (Jackson v. Indiana 1972). In cases where the forensic evaluator believes that a defendant may be incompetent to stand trial, diagnostic and prognostic information may be useful to the court in its determination of the likelihood of competence being restored through treatment.

When questions about a defendant’s competency to proceed arise at any point prior to or within a criminal trial, the court (as provided by statutory language varying from state to state) may order a clinical assessment of competency. The court may appoint experts to conduct the evaluation and testify in the subsequent competency hearing. Such input is usually provided by a forensic psychiatrist, who relies on clinical experience and specific training in competency assessment as well as various standardized instruments in making determinations for the state. When incompetence is determined to be potentially restorable through treatment (e.g., for a psychiatric illness) a defendant may be ordered to specific state facilities for the purpose of restoring competence.

All states have legislation governing the periodic review of persons held for restoration of competence to ensure that such involuntary hospitalization is not continued indefinitely. Statutes allow for the initiation of civil commitment procedures for incompetent persons that pose imminent threat of danger to self or others upon release.

The Supreme Court has articulated a prohibition against executing inmates who become incompetent (Ford v. Wainwright 1986) in states where capital punishment is permissible. While the judicial requirement for competency to participate in criminal proceedings is generally viewed as morally and ethically prudent, considerable controversy exists surrounding the issue of clinical efforts to restore competency (or even evaluate competency) of persons potentially facing capital punishment (Bonnie 1990, Rosner et al. 1991). Critics view physician participation in restoration of competency for the purpose of execution as contradictory to the Hippocratic imperative to “first, do no harm” (Appelbaum 1990). Many states have crafted legislation bifurcating capital trials into distinct guilt/innocence and sentencing phases, allowing the judge or jury to hear evidence regarding mitigating factors (e.g., mental illness) or aggravating factors (including future dangerousness) in determining a sentence (Shawalter and Bonnie 1984). Clinicians asked by attorneys or the courts to become involved in such determinations may choose to defer to forensic psychiatrists, but at a minimum should seek forensic consultation before proceeding with such requests.

**Criminal Responsibility and the Insanity Defense**

Since our legal tradition and common law dictate that a person may only be convicted if it is proven that he performed the criminal act and did so with the requisite “guilty mind,” it follows that a competent defendant may seek acquittal for lack of requisite mens rea. The insanity defense is an assertion that the defendant did not possess a “blameworthy” state of mind at the time of the criminal act. Like competency, insanity is a legal construct rather than a clinical entity. Unlike competency, insanity refers to the defendant’s mental state at the time of the alleged offense. Our society values autonomy—the freedom to make choices—and consequently holds dearly the idea of accountability for one’s choices and behaviors. Societal emphasis on personal accountability is perhaps one reason the insanity defense is among the most controversial concepts in western jurisprudence. In the United States, the legal standard for insanity has been modified in various jurisdictions in recent years and remains variable across states. Since the insanity standard reflects our society’s changing views on the balance between personal accountability and scientific determinism, a review of the evolution of the standard is informative.

Until the 1950s the test of insanity articulated in the 1843 British trial of Daniel M’Naghten for the murder of Prime Minister Robert Peel’s secretary served as the standard for insanity in most states. In this trial, lawyers established that M’Naghten was under the delusional belief that the Pope and Prime Minister were conspiring against him.
A parliamentary inquiry after his acquittal resulted in the following guidance:

to establish a defense on the ground of insanity it must be proved that, at the time of the committing of the act, the accused was labouring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing; or, if he did know it, that he did not know what he was doing was wrong. (Queen v. M’Naghten 1843)

The basic principle underlying the insanity defense articulated in M’Naghten was that of a strictly cognitive test for insanity; that is

1. the presence of a mental disorder or “defect of mind” and
2. a lack of comprehension of the nature or wrongfulness of the act (e.g., “as to not know the nature and quality . . . or what he was doing was wrong”) (Ray 1871).

This standard served as the model for most US jurisdictions through the first half of the 20th century. It was criticized by clinicians and legal authorities with increasing understanding that psychiatric illness might impair a person's ability to apply knowledge—even if he or she satisfied a strict cognitive test of knowing right from wrong. Beginning in the 1950s, states adapted standards incorporating a volitional prong allowing for insanity acquittal if the defendant’s behavior was determined to be the “product” of a mental disease or defect (Durham v. United States 1954). This concept evolved into interpretations allowing for acquittal if the mental disease or defect resulted in “an irresistible impulse to perform the criminal act” (Weinberg 1957), or “substantially impair(ed) behavioral controls” (McDonald v. United States 1962). The American Law Institute (ALI) test that formed the basis for laws in many jurisdictions stated: “A person is not responsible for criminal conduct if, at the time of such conduct, as a result of mental disease or defect he or she lacks substantial capacity to appreciate the criminality (wrongfulness) of his or her conduct or to conform his or her conduct to the requirements of the law” (Model Penal Code 1962). In the 1980s a societal reemphasis on law, order, and discipline (in reaction to the permissiveness of the 1960s and 1970s) was accompanied by recognition of limits of present day science in defining human behavior. Recognition of limits of scientific and medical expertise in determining whether a mental disorder resulted in the inability to refrain from criminal behavior led to revision and modification of these more inclusive standards in many jurisdictions.

Public outrage at the insanity acquittal of John Hinckley after his attempt to assassinate President Reagan precipitated the passage of the Comprehensive Crime Control Act of 1984. The act provides that for persons prosecuted in federal courts, the insanity defense may be asserted only when “the defendant, as a result of severe mental disease or defect was unable to appreciate the nature and quality or the wrongfulness of his acts.” The act also states: “Mental disease or defect does not otherwise constitute a defense.” This stringent standard eliminates any defense based on a volitional standard for insanity. Finally, the act states that the burden of proof is shifted to the defense. The defense must establish, by “clear and convincing evidence” that mental disease or defect rendered the defendant incapable of appreciating the nature and quality or wrongfulness of his acts, rather than requiring the state to prove (beyond a reasonable doubt) that a defendant was sane (Comprehensive Crime Control Act 1984). While the level and burden of proof vary from jurisdiction to jurisdiction, most states have followed the federal lead in adopting more restrictive standards.

Regardless of jurisdiction, the trier (judge or jury) relies on expert psychiatric testimony in deciding insanity defense cases. Court-ordered evaluations of criminal responsibility (or sanity) are most often conducted by forensic psychiatrists. As in the case with competency determinations functional capacity, rather specific diagnosis, is the threshold determination. In criminal responsibility evaluations, the examiner seeks to establish the mental state of the defendant at the time of the alleged offense. Clinical interview and diagnostic evaluations are augmented by review of related medical records, police and investigative reports, and collateral interviews of witnesses (those who may have seen the alleged criminal act, as well as those who had opportunity to interact with the defendant in the weeks, days, hours or minutes before and after the criminal acts).

Psychiatrists in clinical practice are generally concerned with a patient’s perceptions of his or her interactions with others and with the environment or the patient's subjective experiences. Clinicians may rely on collateral information when they believe the patient may be particularly unreliable and safety is an issue. In contrast, the forensic evaluator is asked to determine the “actual” or objective mental state of the defendant at the time of the alleged criminal act or acts. This objective mental state is a component of the “historical truth,” which the forensic evaluator seeks to reconstruct. Persons being evaluated for criminal responsibility are frequently ordered into evaluation (rather than voluntarily

</table>
seeking treatment) and may not inherently trust the evaluator. They may be motivated by the prospect of avoiding criminal prosecution to deliberately embellish or feign symptoms. In forensic psychiatry, particular effort is made to corroborate reports of the defendant and to assess for malingering during clinical interview and through psychological testing. While decisions to initiate treatment in clinical settings may (with informed consent) be based on “the working diagnosis” or the most likely diagnosis based on patient report and physical findings, expert opinion regarding diagnosis, competence, and criminal responsibility in forensic evaluations must be based on “a reasonable degree of medical certainty.” Reasonable medical certainty is not clearly defined in any jurisdiction, but the concept incorporates a threshold level of scientific and objective basis for diagnosis and opinions and that will withstand cross-examination by other experts in the courtroom setting. Table 6–8 summarizes the evolution of the insanity standard.

Clinical Vignette 2

A 38-year-old single man with a history of chronic schizophrenia lives with his grandmother. He is not allowed to live with his parents because of past frequent threats he had made toward them. His aggressive behaviors toward his parents were based on his delusional belief that they were not his real parents, but conspirators in a plot to use his brain for “government mind control research.” He was often noncompliant with medications because he believed that they were dissolving his brain. During one period of medication noncompliance he becomes increasingly confused and concludes that his grandmother must also be a conspirator and secretly putting chemicals into his food or injecting them while he was asleep. He waits for her to go to bed. Once she is asleep he enters her room and beats her repeatedly in the head with a baseball bat until she is dead. He then wraps her body in a blanket and conceals it in the trunk of a car parked in the garage. He destroys the bed linen and remakes the bed. When his parents repeatedly telephone during the next few days he does not answer the calls. They ultimately summon the police who, after and extensive interrogation and search, discover the body.

Upon the advice of his attorney, the man enters a plea of not guilty by reason of insanity. He is evaluated by a forensic psychiatrist appointed by the state who renders the opinion that the man is competent to understand the charges and assist in his defense. The defense attorney argues that because of the severe and chronic nature of his client’s psychotic illness he could not have possibly understood the wrongfulness of his acts—or if he did, he did not have the capacity to plan the murder and should only be found guilty of the lesser included offense of manslaughter. Forensic psychiatrists hired by the prosecution and by the defense testify with opposing views about the man’s capacity to appreciate the wrongfulness of his acts or to form a specific intent.

During his closing arguments, the prosecuting attorney asks the jury for a finding of guilt for the charge of premeditated murder. He urges them to use their own common sense to understand that taking the bat into the room and striking a woman repeatedly in the head with a baseball bat until she is dead. He then wraps her body in a blanket and conceals it in the trunk of a car parked in the garage. He destroys the bed linen, hiding the body, and refusing to answer the telephone (that the man was clearly aware at that time that he had committed a wrongful act.

The judge then instructed the jury on the current standard for mental responsibility for criminal acts. The jury concluded that the man was aware of the wrongfulness of the act at the time he committed it and the jury returned a verdict of guilty for the charge of premeditated murder. During the sentencing phase of the trial, the defense was able to enter evidence regarding the severity of illness, potential of improvement with ongoing supervised treatment, and risk for future acts of violence. After extensive deliberation the jury recommended a sentence of 20 years imprisonment rather than possible maximum sentence of life in prison without the opportunity of parole.

Other Criminal Issues: Diminished Capacity and Mitigating Factors

Diminished Capacity and Mitigating Factors

In some circumstances, the law acknowledges the concept that mental disease or defect may alter the mental capacity of a defendant without completely eliminating appreciation for the nature, quality or wrongfulness of one’s actions as required by the insanity defense. Certain offenses, termed specific intent crimes require proof of a more stringent mens rea than appreciating wrongfulness. For example, the definition of Assault with Intent to Commit Homicide requires the defendant to have acted with the “purpose of killing or committing grave bodily harm” in most jurisdictions. Forensic psychiatrists, in such cases, may testify as to whether clinical evidence suggests that a defendant’s mental disease or defect contributed to actions for which the defendant could not have formed such specific intent. If a mental disease or defect precludes the specific intent of a crime, the defendant is acquitted of that crime, but may be convicted of a lesser crime such as manslaughter (Morse 1984, Melton et al. 1987). Since the law presumes that a person’s intent may be inferred from his actions, it is particularly challenging for defense attorneys to assert the defense of diminished capacity without expert psychiatric testimony. Various jurisdictions have placed limits on whether expert testimony regarding diminished capacity is permissible (Lande and Armitage 1997, Slovenko 1995). As with questions of criminal responsibility, the forensic psychiatrist must evaluate objective evidence of disease state at the time of the offense based on clinical evaluation, record review, crime scene evidence (e.g., investigative summaries and witness accounts) as well as other collateral sources of information.

Other criminal defenses may also benefit from the input of a forensic psychiatrist. Defendants may be acquitted if they can establish that alleged criminal behavior resulted from an automatism—an act occurring in a state of mental unconsciousness or dissociation without purpose or intention. Acts occurring in the context of somnambulism, involuntary movement disorders or seizure disorders, prescription medications side effects, and hypoglycemic states are examples of situations where psychiatric testimony may inform the court and result in acquittal (Low et al. 1982, Devinsky and Bear 1984). Most jurisdictions do not recognize alcohol or illicit drug intoxication as an automatism defense as such intoxication is generally considered a voluntary act.
However, alcoholism and acute intoxication may be considered as determinants of degree of mental capacity for specific intent crimes (Granacher 2004, Merikangas 2004).

The existence of treatable mental disorders, including substance use disorders, and a defendant’s motivation for treatment may also be introduced as factors for consideration in sentencing proceedings (evidence of mitigation or extenuation). The same may be said for various other psychiatric disorders and syndromes for which symptoms are less clearly defined or do not rise to a level necessitating a finding of incompetence or insanity. Examples include “battered woman syndrome,” “battered child syndrome,” “rape trauma syndrome,” culture-bound syndromes, and posttraumatic reactions (Ibn-Tamas v. United States 1979, Sacks 1994, Gallin 1994, Simon 1995). Sentencing proceedings allow for testimony (subject to cross-examination) about a range of issues including the defendant’s psychosocial and developmental environments, lack of access to treatment, and psychiatric prognostic factors for rehabilitation. Accordingly, forensic psychiatrists and treating psychiatrists are often frequently called upon by defense and prosecuting attorneys to inform the judge or jury in the sentencing phase of criminal trials. In situations where a general psychiatrist is asked to participate in such proceedings, it is prudent to consult with a forensic psychiatrist to explore the strengths and weaknesses of any arguments that the court may hear and prepare for the cross-examinational scrutiny that testimony may receive in an unfamiliar adversarial process.

Children and Adolescents
Child psychiatrists often become involved in child custody evaluations (Waller and Daniel 2005, Ackerman and Kane 2002), but they may also be involved in court-ordered assessments of delinquent behavior and consideration for child criminal cases to be waived into the adult criminal justice system. They may be called to participate as witnesses in adult criminal trials involving child or adolescent victims. They may be asked to testify regarding the reliability of child testimony or the psychiatric impact of criminal victimization in the cases of sexual assault or other traumatic exposures (Schetky and Benedek 2002). Although school shootings and other forms of school-related child and adolescent violence are relatively rare, the treatment and management of youths considered at risk for school violence is increasingly a focus for mental health professionals consulting to school systems. Clinicians must recognize the limits of confidentiality when others may be in danger, the limits and conditions of potential treatment (e.g., with or without appropriate support from the family and other school-based resources) and the complications created by competing interests. Pending legal charges against the patient, custody disputes between parents, or potential placement in special education programs or institutions must be considered. For the forensic evaluator, these challenges may also impede comprehensive risk assessment. Both clinical assessment and forensic assessment require comprehensive psychiatric and mental status evaluation, review of collateral information, synthesis of information from a variety of other persons (family members, peers, teachers, school counselors, and law enforcement personnel), and careful documentation (Murakami et al. 2006). Structured assessment tools developed specifically for violence risk assessment may augment clinical and forensic evaluations (Grisso et al. 2001, Catchpole and Gretton 2003). Child psychiatrists participating in such proceedings may also find it prudent to avail themselves to consultation from a growing number of child forensic psychiatrists.

Correccional Psychiatry
There are roughly one million incarcerated adults within the United States at any given time. As many as 20% of inmates in jails and prisons may suffer from serious mental illness (American Psychiatric Association 2000). While less than 5% of those incarcerated in U.S. jails and prisons are women, an estimated one third to two thirds of this group require mental health treatment (Lewis 2006). High rates of major depression, posttraumatic stress disorder, substance dependence, and antisocial personality disorder are present in prison populations (Jordan et al. 1996). In recent years, considerable attention has been devoted to the development of appropriate mental health services and programs for the incarcerated population with a particular emphasis on early assessment and suicide prevention (National Commission on Correctional Health Care 1996, American Psychiatric Association 2000, Metzner and Dvoskin 2004, Scott and Gerbasi 2005). The development of programs and policies that ensure appropriate allocation of available services, address the complex comorbidity observed in many prisoners, and facilitate continued treatment after release are areas of active research.

Although forensically trained psychiatrists often work in correctional settings, the majority of prison psychiatrists, psychologists, and social workers in jails and prisons do not have specific forensic training. Work in these often underresourced and potentially dangerous environments may be particularly challenging. Increasingly, prisoners who are either unable or unwilling to follow institutional rules are placed in disciplinary segregation (solitary confinement or “lockdown”) as a means of punishment, to promote institutional safety, or both. It is widely believed that placement of seriously mentally ill offenders in such environment will result in clinical deterioration and is clinically contraindicated. However, the long-term effects of such segregation on more healthy inmates, the delivery of appropriate therapeutic interventions to prisoners who are placed in segregation units, and the degree to which confinement, social isolation, and relative sensory deprivation must be limited to prevent long-term psychological harm are less clear. Input from appropriately trained and forensically experienced mental health professionals into the disciplinary process with correctional institutions may clinically inform the disciplinary process and enhance safety in correctional institutions (Metzner and Dvoskin 2006).

Conclusion
The practicing psychiatrist is more appropriately concerned with the nuances of clinical presentation, diagnosis, and therapeutic intervention than the forensic aspects of mental health and legal proceedings. The standards for determination of competency, criminal responsibility and the objective analysis of mitigative or exculpatory factors in criminal proceedings fall more squarely within the scope of practice of the forensic psychiatrist. Regardless of interest, clinical psychiatrists must interface with the legal system in situations...
where patients may be dangerous to self or others, or do not demonstrate the capacity to provide informed consent for treatment. Psychiatrists are involved in malpractice litigation less frequently than most other physicians, but they are at particular risk in the aftermath of suicide or as a result of boundary violations. Familiarity with state laws and regulations regarding involuntary commitment, duty to warn, and standards of care is important for all psychiatrists. Consultation with forensic psychiatrists may be helpful in issues related to dangerousness assessment, civil commitment, or potential Tarasoff obligations. Consultation will also help prepare nonforensic psychiatrists for courtroom testimony on civil or criminal proceedings.

A Developmental Perspective on Normal Domains of Mental and Behavioral Functions
The miracle of human development has always fascinated physicians. Psychiatrists and pediatricians have formally studied developmental processes and have used the knowledge gained from these investigations to create more effective strategies for care of patients. With the evolution of the specialty of geriatrics, interest in the developmental changes that occur after having achieved full maturation has further expanded the scope of investigations. With better understanding of the changes that predictably occur in the last half of life, it has become possible to link more effectively early precursors of illnesses to the later expression of developmental delays and deviations.

There are two classical approaches to the study of human development: the stage model and the longitudinal lines of development model. Each has distinct advantages and disadvantages. The more traditional approach is to examine each stage of development. Consequently, the unfolding of the many new capabilities of the infant is reviewed chronologically so that the child as a whole can be better understood. Thinking about development as a series of stages is a particularly useful approach for clinicians and therefore is the primary strategy used to organize this section on human development. There are six chapters that chronologically address the development of (1) infants, (2) preschool children, (3) school-age children, (4) adolescents, (5) adults, and (6) older adults. The reader can turn to each of these chapters and come away with a clear understanding of the developmental changes that occur during each of these stages. Furthermore, the special risks associated with each period of development that are relevant to the onset of psychiatric illness are reviewed.

An alternative strategy used to teach development is to choose a particular aspect of human development and track it from birth until death. This is a helpful strategy for understanding the process of development and is useful for researchers who are searching for the antecedents of characteristics that occur during later developmental periods. However, the accurate charting of these lines of development has proven to be difficult. Clearly, it is not feasible for a single investigator to study the extensive changes that occur over the lifespan. Longitudinal studies that span at least 10 years are usually conducted by a series of principal investigators who work sequentially in order to achieve continuity. Consequently, most investigators become specialists in narrow age ranges of the developmental process and must work collaboratively with colleagues to link together the transitions from infancy to childhood or adolescence to the adult years.

In this chapter, an overview of five prominent lines of human development is presented so that the reader can quickly obtain a sense of the timetable of normal development. These are (1) biological development, (2) cognitive development, (3) emotional development, (4) social development, and (5) moral development.

In addition, a longitudinal review of periods of development that are associated with an increased risk of specific psychiatric disturbances is provided.

There has been a scientific preoccupation with defining the relative contributions of genetic endowment and environmental experience on the course of human development. While early behavioralists took the extreme view that children could be shaped almost exclusively by their environments, contemporary evidence supports the view that genes and experience interact in a transactional manner that leads to the unique development of an individual. The study of environmental contributions has steadily improved through the application of more careful methods of assessment and an appreciation of the value of examining the many components of the early experience of children.

However, the most explosive advances in the understanding of human development have been made, as specific gene variations have been identified and linked to physical and behavioral outcomes. In the past decade, the pace of new gene discovery has increased exponentially as a consequence of the success of the Human Genome Project. It is now estimated that human beings have less than 30,000 genes. Determining the precise number has been elusive, as
it has been necessary to gradually understand that human genes are much more complex than the genes of simpler organisms. Specifically, many human genes produce multiple proteins. We are now learning about the degrees of genomic variability that exist between individuals, as well as beginning to understand how genes interact with each other and how they are regulated by the environment. A key focus of new research is the discovery of how the passage of time and the gradual maturation of the individual affect the expression of genes that have remained silent but potentially ominous from the beginning of fetal development. Future studies of cohorts of infants who are at known genetic risk of a trait or illness may well identify environmental factors associated with both the expression and the suppression of gene expression.

The concept of studying development longitudinally has its origin in the lives described by Plutarch and popularized by Shakespeare. In many ways, biographers strive to examine the origins of adult traits through consideration of the early experiences of their particular subject. This tradition was adopted by psychoanalysts who searched for the origins of psychopathology through the exposition of a “genetic formulation.” The choice of the word “genetic” to describe a conceptual formulation that was created by the experience of the individual is certainly ironic. Nonetheless, this focus on the influence of early experience on development may well have been a foreshadowing of the importance of intense early experience on gene expression. In all likelihood, the genetic formulations of the future will focus on how experience regulates gene expression at the molecular level.

The concept of a parallel yet interacting line of development was popularized by Anna Freud (1946) who created a classical monograph that articulated nine lines of development that were well described through adolescence. Although some of these conceptual lines have been abandoned, the overarching principle of a line of development has proven to have heuristic value. Other developmentalists have built on her model to create parallel developmental lines extending into adulthood. Erikson (1963) further elaborated the evolution of domains of function in the creation of his epigenetic stage model. His paradigm continues to have a strong influence on psychiatric theory, as is well illustrated by the work of Vaillant (1977).

Although lines of development are attractive conceptually, they are deceptively simplistic representations of the complex evolution of personality. The concept of “decalage” was put forward by Piaget (1952) to refer to a disengagement in the normal evolution of the parallel development of specific cognitive abilities. However, decalage is equally salient in the conceptualization of major distortions in emotional or social development. In this chapter, five broad lines of development are reviewed as they evolve over the course of the lifespan. Developmental timelines for each line of development are included. In the following chapters, there is a more detailed discussion of these timelines, as well as a discussion of the interactions that are typical within each stage of development and the stage-specific risk factors.

**Biological Development Genetic Considerations**

The genes that an individual possesses contain all of the information required to define the individual. Some genes have strong penetrance and express themselves in virtually all environments. This is the traditional view of the influence of genes, which, if taken literally, leads to the erroneous conclusion that any genetic influence is immutable. It is now clear that many genes have only partial penetrance and that there are both physical and emotional environmental factors associated with the expression of these genes.

In considering the biological development of an individual, it is apparent that single genes that control such critical functions as physical growth have a high degree of penetrance in a wide range of environments. For example, while malnutrition, maltreatment, and medications can retard growth, genes have a powerful impact on adult height. This is demonstrated by the observation that monozygotic twins are nearly identical in adult height. Interestingly, the same is not true of weight, which suggests that a wider range of environmental factors lead to adult variation in weight. In monozygotic twin pairs, adult weight can vary by more than 20%, although the majority of twins are actually much closer in size.

A timeline of biological development over the course of the lifespan is presented in Figure 7–1.

**Neurological Considerations**

Brain growth is one of the most basic indicators of neurological development. The brain is already at approximately one-third of its adult size at birth, and it grows rapidly, reaching 60% of its adult weight by approximately 1 year and 90% of its adult weight by 5 years of age. The final 10% of growth occurs during the next 10 years with attainment of full weight by 16 years of age. The processes of myelination, synapse proliferation, and synaptic pruning occur in the course of the lifespan, but they are particularly active in the first years of life when the functional structure of the brain is becoming defined. Maximum synaptic density is reached at different development time points in different brain regions. Maximum density in the auditory cortex is achieved by 3 months, whereas maximum density in the middle frontal gyrus is not reached until 15 months of age (Huttenlocher and Dabholkar 1997). After this point, the density of dendritic spines generally decreases as glucose metabolism becomes fully developed. The establishment of biological rhythms occurs in early infancy, as sleep becomes more organized and of shorter nocturnal duration. A stable pattern of temperament cannot be documented in the first months of life, but temperament gradually becomes established during the second year. During the preschool period, individual neurons and neural networks are preferentially preserved if they receive stimulation. Motor skills emerge as a reflection of the underlying neuronal development of the central nervous system.

By the age of 7 years, considerable sensory integration has occurred. Handedness has been clearly established, and brain plasticity has decreased. By 10 years of age, limitations in the ability to learn to speak an unaccented second language reflect further changes in the development of the motor linguistic pathways. In the years of adolescence, full brain weight is achieved, but myelination continues well into the fourth decade. By the end of the fifth decade, there is often evidence of the beginning of decline in specific neuronal functions, with vision and memory being particularly vulnerable. However, integrative capacities may reach a peak during the later decades.
Endocrinological Considerations

While interesting changes in hormonal development occur in the first years of life, dramatic changes in both physical and emotional functions are triggered by the hormonal shifts associated with puberty that characterize the adolescent years. In girls, estradiol and progesterone production results in the onset of breast development, followed by the onset of pubic hair growth and vaginal elongation. Axillary hair subsequently develops during stage 3 of pubic hair development. Although there is wide variability in different cultural environments, menarche is usually attained 2 years after the onset of breast development and has been reported to occur at an average of 12.8 years of age in population studies (Zacharias et al. 1976). In boys, puberty begins when rising levels of pituitary hormone result in enlargement of the testes and subsequent increases in circulating testosterone. Spermatogenesis occurs after testicular enlargement at approximately 14 years of age. Pubic hair development is triggered by adrenal androgens and occurs in five stages during the course of about 2.5 years. Facial hair tends to develop between 14 and 15 years of age.

Growth hormone and gonadal hormones are both necessary to initiate the adolescent growth spurt. This occurs earlier in girls, usually during Tanner’s breast stages 2 and 3, whereas in boys it does not occur until stage 4 of genital development. Both an acceleration of bone growth and a maturation of the skeletal structure as reflected by increased bone density and closing of epiphyses occur during this process.

Sexual function peaks early in the adult years in men, but there is only a gradual decline in sexual function as measured
by frequency of orgasm from 20 to 70 years. Women have consistently lower sexual functioning throughout the childbearing years and frequently become more orgasmic in their 30s. However, decreases in estrogen levels associated with menopause usually occur between 45 and 54 years of age. Men have no comparable menopausal change in hormonal levels.

**Cognitive Development**

The study of cognitive development provides a perspective on the evolution of the capacity to think. Increased cognitive abilities are an integral component required for the onset of language. Changes in thinking ultimately shape the course of emotional, social, and moral development. Recent investigations of the relation of brain development to cognitive development have attempted to attribute specific developmental changes in central nervous system function, with the achievement of new cognitive abilities (Casey et al. 2000, Anderson 2001).

However, the acquisition of mental abilities has been charted as an independent sequence of mental accomplishments. Piaget established the field of cognitive development, and his stage theory of the evolution of cognitive processes has dominated this field (Piaget and Inhelder 1969). Although specific aspects of his four primary stages have been modified by subsequent empirical experiments as well as by the development of a greater appreciation of the role of emotions and context in the utilization of cognitive abilities, his careful observations and deductions have provided the framework on which much of our knowledge of cognitive development has been built. In contrast, Vygotsky (1978) provided a model of early cognitive development that placed greater importance on the influence of culture- and language-mediated guidance by adults.

Piaget introduced the concept of “schemas” that he defined as units of cognition. He further described processes that result in schema modification, which begin in infancy as a child assimilates new information and accommodates to novel stimuli. A particularly important Piagetian concept has been that of a decalage within cognitive development, which refers to an unevenness in cognitive development. For example, a child may demonstrate cognitive abilities at the concrete operational stage of development with regard to conservation of volume and at the same time retain preoperational forms of thinking such as persistent egocentrism. Such an unevenness can also be seen across lines of development.

Even newborns have the ability to learn through making associations between different states or experiences. There is evidence that cognitive “prewiring” exists, which allows for the perceptual capacities of infants that are necessary to seek stimulation and interaction with adult caregivers. A key capacity required for these early cognitions is recognition of the invariant features of perceptual stimuli coupled with the ability to translate these invariant features across sensory modalities. For example, infants can differentiate the human voice from other sounds innately without “learning” the complex characteristics of the structure and pitch of speech.

By 2–3 weeks of age, cross-modal fluency is demonstrated by the ability of infants to imitate facial expression. This requires the recognition of a visual schema of a facial expression to be linked with a proprioceptive tactile schema of producing a facial expression. By 3 months of age, infants can be classically conditioned, and their interest in stimuli led Piaget to suggest that this was a period dominated by attempts to make “interesting spectacles last” (Piaget and Inhelder 1969).

By 6 months of age, associations between “means” and “ends” have been demonstrated. This is followed by object permanence, which evolves during the second half of the first year. During the second year, infants can infer cause after observing an effect as well as anticipate effects after producing a causal action. A corollary of this new ability is that they are now able to correctly sequence past events.

By the third year of life, children enter the preoperational stage. This form of thinking is more similar to adult cognition, but it incorporates magical explanations and is marked by a tendency to focus on one perceptual attribute at a time. Idiosyncratic cosmological theories are common and are usually dominated by transductive reasoning, which attributes causality based exclusively on temporal or spatial juxtaposition. Throughout the preschool period, attention span and memory are limited while pretend play and fanciful thinking are common. Not surprisingly, children having imaginary friends and talking pets characterize this cognitive period. The preoperational stage is also the time during which explosive language development occurs. This development appears to be made possible by a genetically determined capacity for language. However, language development is clearly enhanced by experiential support and parental communication that is sensitive to the child’s ability to process new words and grammatical structure.

By the age of 6 or 7 years, children begin to use operational thinking. The child who has attained concrete operational thought has the ability to conserve both volume and quantity, as well as being able to appreciate the reversibility of events and ideas. A shift from an egocentric perspective results in a new capacity to appreciate the perspective of others. These new cognitive skills demonstrate an ability to engage in logical dialogue and to develop an appreciation of more complex causal sequences. These new cognitive abilities are clearly required for a child to benefit from the grade school curriculum.

Adolescence results in the development of a new processing capacity that involves the manipulation of ideas and concepts. Furthermore, the informational fund of knowledge is dramatically expanded and serves as a referent for verification of new data that are assimilated. A final major transition is possible with the development of the ability to reflect on cognition as a process. This is referred to as the development of a metacognitive capacity. Achievement of this capacity allows adolescents to understand and empathize with the divergent perspectives of others to a greater degree than was previously possible. This capacity is necessary for recursive thinking, which involves an awareness that others can think about the domain of the adolescent’s own thought. These cognitive skills represent the transition into the final stage of cognitive ability, which is referred to as the use of formal operations. One capacity characteristic of this stage is the ability to understand complex combinatorial systems that require a well-developed sense of reversibilities that include inversion, reciprocity, and symmetry. New levels of problem solving are achieved that include the ability to recognize a core problem or core isomorph within a more complex new problem. The adult with formal operational
ability can recognize a previously successful solution and use this knowledge to develop a parallel innovative solution to the complex problem. However, many adults remain at the stage of concrete operations and never develop these capacities.

A timeline of cognitive development during the course of the lifespan is presented in Figure 7–2.

**Emotional Development**

The emotional state of the newborn is largely assessed by facial expression and accompanying vocalizations. However, the communicative capacity of young infants has become increasingly well appreciated. In the first weeks of life, contentment and distress have been reliably monitored (Lewis 1994). These primary emotions further differentiate during the first months of life. By 7–9 months, a transition occurs, which is based on the earliest attainment of intersubjectivity. At this point, infants begin to understand that their own inner experiences and feelings can be appreciated by other individuals (Trevarthen 1979, Emde 1984). This leads to the possibility of developing affect attunement as parents match their own behavior with the behavior of their infant, while experiencing shared internal feeling states. An infant pouting to elicit a parental response evidences the instrumental use of emotions. Social referencing is usually evident by 12 months of age, when infants turn to examine their mothers’ facial expressions at times when they are confronted with potentially fearful situations or objects (Klinnert 1984).

In the second year of life, the rapprochement crisis occurs, as infants become aware of their separateness from...
their primary attachment figure and the limitations of their controls over her/his behavior. After the infant has attained self-cognition, new, more complex emotions of embarrassment and envy emerge that further evolve to feelings of shame, pride, and then guilt by the end of the second year. Object constancy, or the ability to reduce anxiety in response to the separation from the primary caretaker, reflects the association of an emotional state with the memory of the sense of internal security provided by the attachment figure.

During the preschool years, children begin to learn the nature of the relationship between emotions and behaviors. They begin to understand the culturally defined rules associated with affect expression and consequently begin to mask their emotions. This is also the period when the Oedipus impulses are most evident, and children must deal with both their conscious attraction to the parent of the opposite sex and their fear of potential retaliation from the same-sex parent.

As children move into the school years, they experience the full range of adult emotions, although there is at least a qualitative sense that during the prepubertal period there is less intense expression of affect. Although sadness is easily recognized from the second year of life, prolonged periods of depressed affect are rare during this period. However, temperamental styles tend to emerge, and, specifically, behavioral inhibition can become more clearly appreciated within the context of increasing social and educational demands (Kagan et al. 1989).

In adolescence, emotions are more intensely displayed, and there is an emergence of a greater incidence of affective disorder and anxiety. Similarly, there is a dramatic increase in suicidal behavior that is in part associated with cognitive ability. At this point, there is a greater reflection on aspects of existential crisis, which can be experienced from more complex vantage points.

A perspective on the evolution of defense mechanisms as regulators of affect suggests that a hierarchy of more sophisticated and effective defensive strategies emerge throughout adolescence and adulthood (Vaillant 1993). A timeline of emotional development during the course of the lifespan is presented in Figure 7–3.

**Social Development**

It has become widely appreciated that infants are socially interactive from the first days of life. The strong tie that parents feel for their infants has been referred to as the parent–infant bond. Between 7 and 9 months of age, infants develop separation protest and a negative reaction to the approach of a stranger. During the second half of the first year, the attachment of the infant to his or her parents evolves. The primary role of the attachment figure is the provision of a secure base from which the infant can begin to explore a wider social environment (Ainsworth et al. 1978).

It is within the context of the attachment relationship that the first Eriksonian state of “basic trust” is achieved. By 18 months, play begins to be more directed toward peers, but this does not become the predominant form of play until the third year. Along with the striving toward autonomy that characterizes Erikson’s second stage, there emerge more negative affective interactions within the context of the attachment relationship. This phenomenon is widely recognized within the popular culture as the arrival of the “terrible twos.” However, the quality of the attachment relationship earlier in life has been shown to predict better preschool social adaptation and a stronger sense of self-worth. Included in it is the observation that patterns of social dominance become established during the third year of life and that insecure, attached preschoolers exhibit more conflict and aggression in the establishment of their social status. These early social strivings are compatible with Erikson’s third stage, which has as its central developmental objective the achievement of initiative within the context of potential failure and guilt.

Gender differences emerge by 2 years of age. Boys are more aggressive and tend to play with toys that can be manipulated. Girls prefer doll play and artwork. By the end of the third year, gender preference in play has emerged, and the preference is to play with children of the same sex. This preference remains throughout childhood. Associative play, which refers to play that involves other children and the sharing of toys but does not include the adopting of roles or working toward a common goal, becomes more prominent during the preschool years. Cooperative play also emerges along with a strong tendency to include elements of pretend play into the cooperative sequences. The cultural context begins to shape the nature of social interaction even at these earliest stages of development.

During the school years, the role of peers in shaping social behavior becomes predominant. Small groups form, and the concept of clubs becomes important. Shared activities, including the collection of baseball cards or doll clothes, are a common and important characteristic of this period. Sharing secrets and making shared rules also serve as organizing social parameters. Social humor develops, and appearance and clothing become an important social signaling system. It is a time of practicing and developing athletic, artistic, and social skills that are associated with Erikson’s fourth stage of achievement of industry within the context of a sense of potential interpersonal inferiority.

In adolescence and throughout the adult years, social and sexual relationships play a complex and powerful role in shaping experience. With the onset of strong sexual impulses and increasing academic and social demands in adolescence, the role of peer influences in shaping both prosocial and deviant behaviors becomes powerful. Adolescence is the period during which Erikson described the central objective to be the establishment of an individual identity, and there has been wide acceptance of this sense of self occurring within the context of the social and cultural experience. The roles of adulthood are complex and focused on the most basic issues of marriage, parenting, working, and ultimately dealing with death. A timeline of social development during the course of the lifespan is shown in Figure 7–4.

**Moral Development**

The newborn infant lives in an interactive world, but one that is free of moral directives or structure. However, by the second year of life, the emergence of “moral emotions” such as embarrassment, shame, and guilt demonstrates that the beginning of a code of moral behavior, in the most primitive sense, is being established. By 36 months, most children demonstrate the internalization of parental standards even when their parents are not available to provide...
cues or reinforcement. The importance of emotions in the early evolution of moral behavior during the preschool years is particularly important and represents a distinct departure from the more traditional perspective that moral development does not occur until the establishment of concrete operation.

During the school years, the importance of rules and adhering to them become well defined. The moral code tends to be one of absolutes with strong consequences for transgressors. Extreme examples of children turning their parents into authorities because of political resistance provide a sobering perspective on the strength of the convictions of some children. However, for most boys and girls during this period, interpersonal relationships with peers or siblings are a consideration in the determination of “chosen outcomes” when situational paradigms designed to clarify moral priorities are presented (Smetana and Asquith 1994).

The later evolution of moral principles is a complex process. With the development of abstract reasoning, adolescents progress through Kohlberg’s (1964) stages of conventional morality, which entail meeting the expectations of others (stage 3) and subsequently accepting the maintenance of societal norms and rules as an appropriate standard (stage 4). These stages do not progress in a strictly sequential manner. Stages 5 and 6, which ultimately lead to the conviction that moral principles of justice should supersede those of human-made laws, have not been easily codified either, given the influence of complex emotions on behavior and the well-documented moral inconsistencies that occur over the course of adult development (Gibbs 1979).
A timeline of moral development during the course of the lifespan is presented in Figure 7–5.

**Developmental Psychopathology Risk and Protective Factors**

The risk and protective factor model is a paradigm that facilitates the understanding of developmental deviations. It can be applied at any stage of development. In the chapters that follow, the stage-specific considerations that are relevant to infants, toddlers, children, adolescents, and adults are addressed. Risk factors have been divided into three large categories: those at the level of the individual, the family, and the community.

The first category of risk factors is defined at the level of the individual. Both physical and emotional considerations are relevant. Examples include atypical genetic polymorphisms, deficits in perception, and high levels of generalized anxiety. Variable possibilities for adaptation exist, but for a trait or condition to be considered a risk factor there must be a demonstrated increase in the probability of subsequent emotional or behavioral disorder associated with the factor. Furthermore, the pathogenesis of early environmental stressors has been shown to be variable in individuals who have different degrees of genetic vulnerability. This has been demonstrated using developmental analyses of two longitudinal cohorts of children. Variation in the serotonin transporter gene (e.g., SLC6A4) has been linked to depression (Caspi et al. 2003) and variations in the monoamine oxidase A gene (e.g., MAOA) have been linked to a range of behavioral problems (Caspi et al. 2002, Kim-Cohen et al., 2006).
Of particular interest, these studies suggest a gene–environment interaction (Rutter et al. 2006) and the possibility that environmental risk factors such as the use of cannabis can have a differential effect in children with different genetic vulnerabilities (Caspi et al. 2005).

The second category of risk factors is conceptualized at the level of the family. One of the classic examples of a familial risk factor is a parent with a serious mental illness. It is difficult to define the mechanism by which this risk is transmitted. Each parent provides exactly one-half to their genome of the child. However, parents are also in a powerful position to shape the early environment of their children. The full range of family risk factors is quite broad and extends beyond the influence of single individuals within the family to include the impact of family dynamics, which influence the development of the child. For example, a scapegoated child in a family environment who tolerates overt child maltreatment is at particularly high risk of developing psychopathology. While for many years it has been appreciated that unhappy parental separation is a major risk factor for children and even young adolescents, it has only been in recent years that vulnerability to separation has been demonstrated to be partially heritable (O’Connor et al. 2003).

The third category of risk factors is defined at the level of the community. Discrimination based on ethnic or racial status falls into this group of risk factors, as does social disadvantage. Although there is little controversy regarding the negative consequences of discrimination and poverty, the quantification of this risk has been problematic. Community
risk factors rarely occur in the absence of individual and familial risk factors, making it difficult to fully understand their specific influence.

One strategy that has been used to determine the overall risk for developmental psychopathology is to add up the specific factors that a child must deal with, creating an adversity index. This has been accomplished for young children (Sameroff 1986) as well as applied to risk factors occurring later in development (Rutter 1985a, 1985b). Most individuals can cope with a small number of risk factors, particularly if protective factors are also present. However, under the weight of multiple risk factors, most individuals begin to show signs of disturbance. Sophisticated research designs have been developed to estimate relative contributions (Topolski et al. 1997). Curiously, the quantitative effects of protective factors have been less extensively studied, although investigations into the life course of resilient individuals provide some understanding of these factors (Mrazek and Mrazek 1987).

Resilient children represent one of the most fascinating opportunities to understand the mechanisms by which risk and protective factors interact. The study of the children of mothers with schizophrenia or bipolar disorder has been an area of investigation that is of particular interest to psychiatrists. Perhaps this is because these children have been perceived to have had both a high risk for the inheritance of genes that confer poor adaptive skills and the misfortune of having a parent with impaired capacities for sensitive responses to their early developmental needs. While twin studies have suggested that resiliency may be in part heritable (Kim-Cohen et al. 2004), what is striking is that some of these children turn out to be productive and happy adults despite what appears to be overwhelming odds.

A timeline of the development of psychopathology during the course of the lifespan is presented in Figure 7–6.

**High-Risk Periods for Psychopathology**

Psychiatrists who treat children and adolescents are particularly aware of the precursors and onset of psychiatric illnesses. Two examples of age-specific vulnerabilities are discussed, but Figure 7–6 gives an overview of the periods of most probable onset for many of the major psychiatric disorders. The first example is autism, which is unusual in both its invariant early onset and its striking presentation. The second is suicide, which is particularly interesting because of episodic periods of particularly high risk during the developmental course.

Autism is a disease of early onset, which has been shown to have a strong genetic basis. Nevertheless, the role of the environment in affecting the onset of autism is still striking, as demonstrated by the quite dramatic variability in the symptom presentations and ultimate adaptations of monozygotic twins. Autistic children appear normal at birth. During their first months of life, they begin to develop severe deficits in their capacity to form relationships and communicate with others. Once fully expressed, autism has a devastating impact on the subsequent development of afflicted children. What is perhaps most striking is the inevitability of early expression, as there are no examples of onset later in childhood or adolescence.

Suicide provides a sharp contrast to autism. Suicide is highly associated with mental disorder in general and affective disorder in particular. It has also been shown to be moderately heritable. Whereas the onset of suicidal thoughts does occur in rare cases in the preschool period, the capacity to commit suicide increases with age. After puberty, the rate of suicide increases nearly 10-fold. The underlying explanation for this dramatic increase is complex and involves consideration of risk factors at the level of the individual, family, and community. However, the ultimate life course pattern is striking, as there is a second dramatic increase in suicidality in the later years of life. The explanation for this second increase usually focuses on the increase in medical problems of the elderly, but the multiple emotional losses of these years also provide a vulnerable context for depression and despair.

**Interlineal Decalage**

Piaget (1969) defined uneven developmental progress of specific cognitive abilities as a decalage. Psychiatrists must often help patients deal with a decalage across lines of development. Although the chapters in this section are largely devoted to the explanation of normal development, there has been a systematic effort to illustrate how deviations in development may lead to the onset of developmental psychopathology. Normality can be defined as a multilinear progression of development without a decalage, or unevenness of progress, across any of the primary domains of function. Normal children learn to think, to make friends, to deal with intense affects, and to honor the customs of their society. Problems occur when development is uneven. The patterns of these interlineal decalages are varied, and their complexity is, in large part, one of the persistent areas of fascination for psychiatrists. To illustrate this process, two straightforward decalages are discussed. Finally, a more complex example of a severe arrest in development is presented.

Cognitive delays can result in a decalage in which a teenager has the mental capacity of a second grader, while having the sexual urges and emotional swings of a normal adolescent in high school. The cognitive ability of such a teenager may not be perceived as abnormal in the context of a protected classroom. However, within the general population, he/she will be clearly labeled as deviant and will be at high risk of experiences that will place him/her in jeopardy for negative social and academic outcomes. Beyond the obvious limitations in achievement that must be dealt with, there are also emotional risks to be considered if intellectual limitations cannot be placed within a context that protects such an adolescent from ridicule and humiliation.

Emotional delays provide a similar potential for a variety of decalages. A child who is cognitively normal or even precocious may remain emotionally immature. The decalage can be widened if intensive academic effort and subsequent successes become the predominant strategy that the child develops for dealing with social awkwardness or peer rejection. Temper tantrums that were expected in the early years become less easily tolerated in the child “genius” who repeatedly demands to have family and social events orchestrated on her or his terms. In more severe cases, frustration and despair may interfere with adaptation in the same way that they do in the child who is cognitively delayed.

If a domain of function becomes arrested, the decalage becomes more severe. In these cases, overt psychopathology
often results. A clear example is the development of conduct disorder and, subsequently, antisocial personality disorder. In these individuals, physical, cognitive, and social developments appear to be progressing well, but a specific deficit in the development of moral judgment occurs. In some cases, the deficit is best described as the persistence of an immature sense of right and wrong, but in other adolescents there is a deviant development of amorality that is abnormal at any stage of development. Given the resistance of adults with antisocial personality disorder to current treatments, there is a strong case for focusing on the origins of this developmental decalage with the expectation that earlier intervention may be more effective.

The Psychiatrist as a Developmentalist
All psychiatrists inevitably become students of development. The life histories of their patients demand developmental formulations to achieve a sense of understanding of the origins of the presenting symptoms and disturbing behaviors that bring the patients to psychiatric treatment. Perhaps one of the most poignant examples is Huntington’s chorea. The gene that causes this disease has been identified, and it is possible to know accurately whether an infant is destined to struggle with the symptoms of this crippling disability for many decades in the future. Yet it is the life experiences of this individual that shape many of the coping strategies that determine the ultimate outcomes of these future struggles.
Anticipating the challenges of later life and understanding the origins of the strengths and weaknesses of each patient are at the core of the therapeutic process, whether it involves influencing the balance of the central neurotransmitters or identifying and supporting available community resources.

Vaillant GE (1977) Adaptation to Life. Little, Brown & Co, Boston, USA.

For most clinicians treating individuals suffering from psychiatric disorders, early development is of great interest. How did the disorder begin? Were there early biological or psychosocial risk factors that could have led to early identification of the disorder or even its prevention? Is there anything unique or more important about events occurring in the first 3 years of life compared with other years of development with regard to the ontogenesis of psychiatric disorders? More broadly, how do patterns of behavioral adaptation follow particular developmental trajectories, and what factors are most influential with regard to establishing those trajectories?

Many factors may contribute to clinicians’ interest in early development, and new knowledge from research on infant development in the past 35 years has afforded greater insight into clinical issues. Theories of development, which guided the teaching of clinicians for many years, have been supplemented, revised, and in some instances supplanted by data from scientifically rigorous investigations in developmental and cognitive psychology, ethology, neurobiology, chronobiology, behavioral genetics, neuroimaging, and linguistics. Greater collaboration among researchers, clinicians, and theoreticians from these diverse disciplines has led to exploration of increasingly rich, interesting, and pressing clinical questions. Researchers who study infants are now attempting to characterize and measure formerly unapproachable constructs such as relationships and the dimensions of subjective experiences. These developments have made possible new insights in the realm of infant development, while also enriching our understanding of clinically relevant issues.

In this chapter, we present a broad overview of research on infant development relevant to clinical work on infancy and later phases of life. First, we briefly describe influential theories and models of development. Then we trace various lines of development through the first 3 years of life. Next, we consider various risk and protective factors as they affect infant development. Finally, we consider selective examples of psychiatric disorders that occur in infancy to illustrate clinical application of developmental findings. Three overarching points are emphasized throughout. First, infants are active participants in their development, and individual differences in their characteristics and capacities have important implications for how infants are experienced by their caregivers. Second, the caregiving environment is the crucible within which individual differences in development in the first 3 years of life are shaped, preparing infants for transition to the broader influences of the preschool years and beyond. Finally, development occurs within the enabling or limiting multiple dynamic contexts of biology, relationships, culture, and technology.

**Theories and Models of Development and the First 3 Years of Life**

**Theories of Development**

Theories are important to the study of development for a number of reasons. They organize and prioritize large
amounts of data regarding infant development, indicating which are the most salient and why. Often, they also explain the importance of the early years for subsequent development, indicating how developmental issues are related to broader issues of the lifespan. Generally, they move from beyond mere descriptions of behavior and attempt to explain why individuals are motivated to behave in certain ways at certain times. Finally, they may generate meaningful and testable hypotheses for empirical research.

On the other hand, theories also have inherent liabilities. The root word for theory is “themai” meaning “to behold,” and so theories are framed from a particular point of view, often with specific agendas. A selective focus on one theory may obscure others of equal or greater value. Theories also inevitably lead to oversimplification of complex processes and events. They may create biases that affect how we interpret observations and how we make inferences from these observations. The history of psychology is filled with examples of adherence to a particular point of view, making it impossible to see disconfirming information. All of these factors urge us to be cautious about the uncritical use of theories to understand development. We believe that a useful theory is one which is developmental, integrative, contextualist, constructionist, and perspectivist in nature, discounting its own absolute claim to truth and integrating as many relevant approaches as possible. An integrative developmental theory accounts for the dynamic interactions of biology (including neuroanatomy, genetics, neurotransmitters, etc.), relationships (including parental, sibling, peer, and wider social groups), culture (including cultural norms for individual and collective development), and technology (including medication, informatics, etc.) (Wilber 2000).

Table 8–1 presents a brief summary of some of the major theories of development as they pertain to the first 3 years of life. Although others could have been selected,
those presented have been most influential with regard to clinical practice and research on early development. As noted in Table 8–1, the theories vary with regard to their particular focus of development, although most use stages to describe periods of discontinuity.

**Models of Development**

Whereas theories of development describe the evolution of particular issues such as cognition, aggression, attachment, or the sense of self, models of development are more concerned with the process by which development proceeds. How do individuals change or remain the same over time? What drives both continuities and discontinuities in development? Although it is common to suggest that we are now beyond nature-nurture conflicts, this ancient debate actually continues in every aspect of science concerned with human development. Although most extreme positions in the debate have been eliminated, the weight that different clinicians, investigators, and theorists give to environmental or to genetic influences varies enormously.

The field of behavioral genetics has made some important and even surprising contributions to this debate. Studies of twins and adopted siblings are able to determine the proportion of variance in various outcomes explained by genes, by shared environment, and by nonshared environment. Shared environment includes all aspects of environmental contributions that two individuals in the same family have in common, such as social class, family warmth, and neighborhood. Nonshared environment refers to the aspects of environmental contributions that are unique and nonredundant for an individual, such as unique aspects of relationships with parents, peer relationships, and unpredictable life events. There is considerable evidence to suggest that for the broad areas of intellectual capacities, personality traits, and many types of psychopathology nonshared environmental contributors are more important than previously recognized. For

<tbody>
<tr>
<td>Attempted to describe the unfolding of innate drives, whose objects progressed from oral to anal during first 3 years of life</td>
<td>Most sophisticated and comprehensive theory of human behavior ever developed. Accounts for the irrational component of behavior through construct of unconscious, which has been widely accepted. Clinically useful and generative, linked to important treatment concepts and techniques</td>
<td>No systematic evidence for fixation-regression model. Constructs not well operationalized and as a result many of its major premises are untestable. Exclusive focus on aggression and libido as motivators of behavior to the exclusion of other seminal constructs. Derived in large part from reconstructive method and from populations of patients. Mechanistic view of person motivated by tension reduction</td>
</tr>
<tr>
<td>Concerned with how infants construct, organize, and transform information</td>
<td>Most comprehensive theory of cognition ever proposed. Based on observable behaviors and replicated cross-culturally. Describes qualitative differences in how children think</td>
<td>Stages imply qualitative changes that are not always supported by data. Theory ties clinical issues to particular stages of development. There are few efforts at validation of first two stages, and clinical implications are not well articulated</td>
</tr>
<tr>
<td>Accepted Freud's drive model but placed developmental issues in a social context</td>
<td>Places Freud's intrapsychic metapsychology in a social context and introduces issues that are more obviously salient than psychosexual stages (trust instead of orality)</td>
<td>Presupposes what it purports to demonstrate that psychological birth gradually unfolds during first 2 years of life. Accepts fixation-regression. Logical inconsistencies. Derived in part from study of deviant behavior</td>
</tr>
<tr>
<td>Also accepted drive model but focused on emergence of psychological self, which she believed was not differentiated until the later part of the second year of life</td>
<td>Deals with fundamental human dilemma of how to be with others and how to be alone. Developed in part from observing normal infants. Moved psychoanalysis to a focus on self-development</td>
<td></td>
</tr>
<tr>
<td>Described the development of attachment, a biologically endowed motivational system responsible for maintaining felt security</td>
<td>Careful attention to observable behavior. Has inspired more research than any other developmental theory. Describes how individual continuity occurs within model of developmental change. Major premises confirmed in cultures around the world. Places emotional intimacy as centerpiece of interpersonal relatedness</td>
<td>Limited to one domain of infant–parent relationships. Overstates importance of early separations. Minimal attention to individual differences in infants as contributors to attachment</td>
</tr>
<tr>
<td>Concerned with how the infant subjectively experiences the world; senses of self continue to function throughout the life span once they are formed</td>
<td>Clear focus on subjective experience of infants in relationships. Abandoned stages in favor of model in which new capacities are added rather than effacing away older capacities. Freed clinical issues from being tied to particular stages in development. Derived primarily from empirical studies of development</td>
<td>Clinical implications not well developed. Does not account for fantasies and distortions by infants</td>

Chapter 8 • Infant Development: The First 3 Years of Life
example, heritability estimates of separation-anxiety in boys range from 0 to 19%, with the major factor being nonshared environmental factors (Topolski et al. 1997). What matters most for a particular infant’s development is not the general characteristics of family size, income, or warmth, but instead the particular ways in which the family relates to that child.

Despite these contributions, behavioral genetic formulations are limited to explaining proportions of variance in relation to a particular outcome. They say nothing of the actual gene–environment transactions that underlie development. It now appears that gene–environment transactions are extraordinarily complex, with genes switching on and off at various points in development, often in response to various environmental perturbations (Sameroff 1997). Research associated with the human genome project may begin to fill in some of these important gaps in our understanding of developmental processes. It appears that many psychiatric syndromes do not exhibit simple Mendelian genetics, but rather poly- or oligogenic inheritance, incomplete penetrance, variable phenotypical expression, or genetic heterogeneity (State et al. 1997). It may also be that the genetic factors contributing to many psychiatric disorders will be “normal variants” of genes, with a particular combination of alleles needed to confer susceptibility to a disorder. This is not unlike the contribution of environmental risk factors discussed later in this chapter.

**Transactional Model**

Linear biological models suggest that insults at an early age might be expected to lead to adverse outcomes. This suggests that we should look for biological markers in infancy for subsequent emotional, behavioral, and cognitive disabilities. Nevertheless, longitudinal studies of child development suggest that biological risk factors considered alone are not strongly predictive of outcomes. Sameroff (1997) cited one study in which the importance of 169 biomedical and behavioral variables assessed in infancy was examined in relation to cognitive outcome of over 25,000 children 4 years later (Broman et al. 1975). Although only 11 of the 169 variables involved family factors, parental social class and mother’s educational level were more predictive of outcome than all biological risk factors combined.

These and related results have led to the creation of linear environmental models of development. Here the idea is that the child’s outcome is shaped by the quality of the caregiving environment. There is, in fact, abundant evidence that the environment contributes powerfully to the infant’s outcome. Nevertheless, ample data also indicate that early adverse environments are not linked in straightforward ways with poor outcomes (Rutter 1989). For example, the Kauai Longitudinal Study followed children at high clinical risk from the age of 2 years through adulthood and found considerable variety and complexity of interactions among environmental factors (Werner 1993). Similar results from other studies suggest that linear environmental models are as inadequate as linear biological models.

Sameroff and Chandler (1975) proposed the transactional model of development in which genetic and environmental regulators of an individual’s behavior transact continually over time, mutually influencing one another. In fact, Sameroff (1997) has posited that much as the genotype acts as the biological regulator of infants’ behavior, the environtype acts as the social regulator of infants’ behavior. For infants, the environtype comprises the cultural, familial, and parental characteristics that regulate infants’ experiences and opportunities. This model describes individuals transacting continually with genotypic and environotypic regulators over time. Behavior at any point in time is a result of the dynamic interplay of genotype, environtype, and individual.

The transactional model is currently the most widely accepted description of the developmental process. It appears to account reasonably well for most developmental outcomes that have been studied except for those that follow the extremes of biological insults, such as certain chromosomal disorders or extreme environmental adversities, such as intense deprivation. Still, the transactional model does not give predictive weight to any particular set of risk or protective factors, and the search for more precise predictive models continues.

**Cultural Context of Development**

One of the most important contexts for development is that of culture, which influences not only the developmental process but also the variables we choose to study it. There is increasing recognition within the behavioral sciences that in a country as culturally diverse as the US, we must face the challenges of better understanding, interpreting, and appreciating cultural diversity as it affects developmental processes. Cultural theorists also remind us of the important influences of culture and technology (Lewis 2000).

Culture refers, as stated above, to a shared system of beliefs, attitudes, and values that characterize a particular social group who share a common history and heritage. Culture includes the worldview of the group and describes normative assumptions that provide individuals within the group with a frame of reference for developing their own values and beliefs. Culture is crucial to understanding development, because one of the major means of transmitting cultural meanings, assumptions, and values is from caregivers to children during child-rearing (Berg 2000). From these descriptions, culture appears to stand as a static cultural construct, when, in fact, it is also dynamic and coevolves within the broader cultural context, especially in these days of simplified individual and technological transportation.

Sameroff and Fiese (2000) have emphasized the role of the cultural code in regulating development through processes of socialization and education. They believe that culture sets the broad developmental agenda for child-rearing, with individual differences apparent within the broad framework. A number of investigators of cultural influences on development provide support for these assertions.

Garcia-Coll and Meyer (1993) have drawn several conclusions from their overview of some of the major research findings from investigations of cultural differences and similarities in child-rearing and their implications for infant development. First, despite enormous differences in child-rearing techniques around the world, parents are motivated to do what is best for their children. Second, despite differences in child-rearing, there is remarkable consistency of some aspects of development across cultures, such as attaining communicative, intellectual, and social competence, although the meanings of what is competent may differ considerably. Third, the timing, content, and expression of developmental processes vary widely across different
cultures. Finally, there appears to be a universality of gender differences in cultures around the world, with boys being more aggressive and girls being more nurturing.

This raises the question of what other universals exist with regard to development across different cultures. LeVine (1977) suggested that there exists a universal hierarchy of parental goals that guide child-rearing behavior. At the most basic level, parents are concerned about developing children’s capacities for self-maintenance as adults. At the next level, parents are concerned about developing children’s capacities for economic self-maintenance as adults. Finally, parents are concerned with developing their children’s cultural values. There is a developmental sequence implied in this model, in which the first goal takes precedence over the other two and is the first major concern of parents in the child’s first years of life.

The application of cultural universals may well be limited, at least beyond the broad outline provided by LeVine. What may be more important from the clinical perspective is identifying within-cultural deviance from the broadly accepted norms, with less regard for the content of the norms themselves.

**Conceptual Framework**

To describe the details of psychological development within the first 3 years of life, we selected the following lines of development with regard to their continuities, discontinuities, and content. These lines are biological–neurological, referring primarily to the brain and central nervous system development and temperament; cognitive, referring to individual changes in intellectual capacity and modes of thinking; emotional, including the differentiation of discrete affects and emotional expression; communicative, referring to understanding of and use of preverbal and verbal modes of communication; and social, referring to all aspects of relatedness and affiliative behavior with others. Discussing these lines separately has some heuristic value, although all the lines of development are interwoven and interdependent such that changes in one resonate through the others.

Rather than discussing each line of development in succession from the birth to 3 years, we review findings relevant to each of the developmental lines within the four different periods. These epochs are defined by three major periods of qualitative reorganization or discontinuity in infancy: 2–3 months, 7–9 months, and 18–20 months. (Table 8–2 summarizes emerging patterns of behavior at different points during the first 52 weeks of life.) These epochs describe different periods of qualitative change in biological, cognitive, emotional, communicative, and social development in which new capacities for experiencing and relating emerge and are different in kind, rather than amount, from earlier capacities. Thus, development between these points consists primarily of quantitative changes, whereas development across these points results in qualitative changes. See Figures 8–1 to 8–4 for a summary of these developmental transitions.

It is important to acknowledge that the transition points can also be overemphasized. By focusing on these major transition points, their importance may be exaggerated at the expense of more minor transitions that are salient for some particular domain of development at a particular point in time. Nevertheless, there is considerable evidence that these specific developmental transitions include observable changes in cognitive, emotional, communicative, and social development (Stern 1985).

**Lines of Development and Their Discontinuities**

**First 2 Months of Life**

The first 2 months of life were once considered a period of psychological inactivity or at least incomprehensibility. William James (1890), for example, considered the newborn to be a “blooming, buzzing confusion.” In the conceptualizations of learning theorists, the newborn was a passive recipient of external influences, a tabula rasa or blank slate, on which the environment drew particular characteristics. Following Freud’s ideas about a stimulus barrier, which was postulated to protect a young infant from potentially overwhelming environmental input, Mahler et al. (1975) described the first 2 months of life as the relatively “autistic” phase of development.

All of these views of the first 2 months of life have been challenged by creative and careful experimental work that began in the late 1960s and 1970s. From this work has emerged a new view of the human infant as a perceiving, remembering, organizing, regulating, and communicating individual. Nevertheless, the first 2 months may be thought of as a period of stabilization for infants as they adjust to postnatal life. During this period of stabilization, infants do not undergo major transitions or reorganizations but appear to consolidate prenatal changes in neurological and psychological development.

**Biological–Neurological Development**

Although birth is a dramatic transition, change at the level of neuroanatomy and neurophysiology is much less striking. Brain growth and specialization, which began in fetal life, continue after birth; in some areas more sophisticated associative pathways continue to develop for many years. Cell migration is completed by the sixth prenatal month, and cell differentiation follows. Over the course of development, cells develop axons and dendrites, make abundant synapses, lose connections (synapse pruning), and become myelinated. Synaptogenesis, pruning, and myelination have variable courses of development, depending on what part of the brain is developing. Overall, the structural development of the brain is completed largely before birth. However, the functional development of the brain is made possible by the selective strengthening and pruning of synapses and circuits through experience with the environment (Nelson and Bosquet 2000). During the first 2 months of life, however, changes in these domains are generally quantitative rather than qualitative and are due to the growth of synapses rather than the birth of new neurons. Positron emission tomography (PET) scan studies of glucose metabolism are fairly consistent with the highest degree of activity in primary sensory and motor cortex, thalamus, brain stem, and cerebellar vermis, and a relatively high level of metabolism in the cingulate cortex, amygdala, hippocampus, and basal ganglia, with a relative paucity of metabolism over most of the cerebral cortex (Chugani 1994). These findings are consistent with the relatively limited behavioral repertoire of newborns with intrinsic brain stem reflexes and limited visual–motor integration.

On the other hand, growing physiological stability becomes apparent within a few days after birth. In this case, interaction with the environment facilitates the rhythmic
Table 8-2
Emerging Patterns of Behavior During the First Year of Life

<table>
<thead>
<tr>
<th>Neonatal Period (First 4 Weeks)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Prone: Lies in flexed attitude; turns head from side to side; head sags on ventral suspension</td>
</tr>
<tr>
<td>Supine: Generally flexed and a little stiff</td>
</tr>
<tr>
<td>Visual: May fixate face or light in line of vision; “doll’s-eye” movement of eyes on turning of the body</td>
</tr>
<tr>
<td>Reflex: Moro’s response active; stepping and placing reflexes; grasp reflex active</td>
</tr>
<tr>
<td>Social: Visual preference for human face</td>
</tr>
</tbody>
</table>

At 4 Weeks

| Prone: Legs more extended; holds chin up; head lifted momentarily to plane of body on ventral suspension |
| Supine: Tonic neck posture predominates; supple and relaxed; head lags on pull to sitting position |
| Visual: Watches person; follows moving object |
| Social: Body movements in cadence with voice of other in social contact; beginning to smile |

At 8 Weeks

| Prone: Raises head slightly farther; head sustained in plane of body on ventral suspension |
| Supine: Tonic neck posture predominates; head lags in pull to sitting position |
| Visual: Watches person; follows moving object 180 degrees |
| Social: Smiles on social contact; listens to voice and coos |

At 12 Weeks

| Prone: Lifts head and chest, arms extended; head above plane of body on ventral suspension |
| Supine: Tonic neck posture predominates; reaches toward and misses objects; waves at toy |
| Sitting: Head lag partially compensated on pull to sitting position; early head control with bobbing motion; back rounded |
| Reflex: Typical Moro’s response has not persisted; makes defensive movements or selective withdrawal reactions |
| Social: Sustained social contact; listens to music; says “aah, ngah” |

At 16 Weeks

| Prone: Lifts head and chest, head in approximately vertical axis; legs extended |
| Supine: Symmetrical posture predominates, hands in midline; reaches and grasps objects and brings them to mouth |
| Sitting: No head lag on pull to sitting position; head steady, tipped forward; enjoys sitting with full truncal support |
| Standing: When held erect, pushes with feet |
| Adaptive: Sees pellet, but makes no move to it |
| Social: Laughs out loud; may show displeasure if social contact is broken; excited at sight of food |

At 20 Weeks

| Prone: Rolls over; pivots; crawls or creep-crawls (Knobloch) |
| Sitting: Sits briefly, with support of pelvis; leans forward on hands; back rounded |
| Motor: Creeps or crawls |
| Adaptive: Sees pellet, but makes no move to it |
| Social: Laughs out loud; may show displeasure if social contact is broken; excited at sight of food |

At 24 Weeks

| Sitting: Sits up alone and indefinitely without support, back straight |
| Standing: Pulls to standing position; “cruises” or walks holding on to furniture |
| Motor: Creeps or crawls |
| Adaptive: Sees pellet, but makes no move to it |
| Language: Polysyllabic vowel sounds formed |
| Social: Laughs out loud; may show displeasure if social contact is broken; excited at sight of food |

At 32 Weeks

| Sitting: Sits up alone and indefinitely without support, back straight |
| Standing: Pulls to standing position; “cruises” or walks holding on to furniture |
| Motor: Creeps or crawls |
| Adaptive: Sees pellet, but makes no move to it |
| Language: Polysyllabic vowel sounds formed |
| Social: Laughs out loud; may show displeasure if social contact is broken; excited at sight of food |

At 40 Weeks

| Sitting: Sits up alone and indefinitely without support, back straight |
| Standing: Pulls to standing position; “cruises” or walks holding on to furniture |
| Motor: Creeps or crawls |
| Adaptive: Sees pellet, but makes no move to it |
| Language: Polysyllabic vowel sounds formed |
| Social: Laughs out loud; may show displeasure if social contact is broken; excited at sight of food |

At 48 Weeks

| Sitting: Sits up alone and indefinitely without support, back straight |
| Standing: Pulls to standing position; “cruises” or walks holding on to furniture |
| Motor: Creeps or crawls |
| Adaptive: Sees pellet, but makes no move to it |
| Language: Polysyllabic vowel sounds formed |
| Social: Laughs out loud; may show displeasure if social contact is broken; excited at sight of food |

At 52 Weeks (1 Year)

| Sitting: Sits up alone and indefinitely without support, back straight |
| Standing: Pulls to standing position; “cruises” or walks holding on to furniture |
| Motor: Creeps or crawls |
| Adaptive: Sees pellet, but makes no move to it |
| Language: Polysyllabic vowel sounds formed |
| Social: Laughs out loud; may show displeasure if social contact is broken; excited at sight of food |

phase with one another has led to interest in infants’ states of consciousness and arousal.

The newborn’s day and night are spent shifting between six states of arousal, listed in Table 8–3. At first, there is little stability in the duration of these states, although from birth there is some order in the direction of transitions between them. Compared with the two sleep states, which occupy two-thirds of the newborn’s day, the awake states are particularly unstable in the first few weeks, although they become progressively better organized and more sustained during the second month of life (Anders et al. 1983).

Dyadic interaction—reciprocal behavior between infant and caretaker,—although once considered minimal or superfluous during this period of development—is probably of significant importance in regulating development of neural mechanisms that modulate and control central nervous system arousal. Caregivers regulate the newborn’s behavioral, neurochemical, autonomic, and hormonal functions through different aspects of the relationship, such as the provision of nutrition, warmth, sensory stimulation, and especially rhythmical responsiveness (Anders and Zeanah 1985).

Rhythmicity is a behavioral referent to hypothesized differences in the central nervous system that are often referred to as “temperament.” All major theories of temperament suggest that temperamental dispositions are rooted in biological differences (Goldsmith et al. 1987). Although individual differences in newborns have been widely demonstrated, there is only modest convergence of measures of temperament (Goldsmith et al. 1987). In other words, meaningful differences in temperament appear to be difficult to ascertain within the first 2 months of life (Woroby 1986). This is not surprising given that behavioral genetics research comparing monozygotic and dizygotic twins has demonstrated virtually no genetic contributions to temperament in newborns (Riese 1990).
Cognitive Development

The human infant has a remarkable ability to learn through perception, discrimination, and indication of preference. Newborns (and even third-trimester fetuses) can be conditioned to auditory stimuli successfully and reliably. Infants at birth seem to prefer female voices, but they also “work” by nonnutritive sucking to recordings of their mothers’ voices in preference to another woman. DeCasper and Spence (1986) reported that when mothers read Dr Seuss’ *The Cat in the Hat* to their fetuses once a day during the last 6 weeks of pregnancy, newborns found that story much more familiar (as detected by patterns of nonnutritive sucking) than another story also read by their mothers soon after birth. This suggests that fetuses’ early preference for their own mothers’ voices may have developed as a result of hearing them *in utero*.

Early recognition in the olfactory domain also indicates newborn recognition of the mother. MacFarlane (1975) demonstrated that 6-day-old infants reliably discriminated the smell of their mothers’ milk. When the breast pad of a 6-day-old nursing infant’s mother and the pad of another lactating woman were placed on either side of an infant’s head, the infant turned preferentially toward the mother’s pad. In addition, 4-day-old infants can discriminate between their mothers’ amniotic fluid, colostrum, and milk, and show a preference for amniotic fluid and colostrum on day 2 and milk on day 4 (Marlier et al. 1998). These behaviors may contribute...

Importantly to parents’ beliefs that their infants recognize them.

In addition to the capacity for rapid learning, research has documented that human newborns are born with a sophisticated biological endowment that Stern (1985) has called their “prewired knowledge” of the world. This knowledge consists of curious perceptual capacities enabling them to seek stimulation actively, to regulate their environment, and to interact with adult caregivers. At the core of these capacities is a remarkable ability to detect the invariant features of perceptual stimuli and to translate the invariant features across different sensory modalities.

Gaze fixation and visual following of the face, as documented by Fantz (1964), demonstrate that infants possess an unlearned preference for visual stimuli that conform to the characteristics of the human face. By 1 month of age, infants demonstrate by differential looking times that they can distinguish the features of their mothers’ face from that of an unfamiliar woman.

A similar case holds for auditory stimuli. Infants are born not only with a preference for the human voice but also with a preference for voices in the usual pitch ranges of females rather than males. Infants are able to recognize innately that speech is a special class of acoustic signal and that language is composed of discrete units (Eimas and Miller 1992). This is quite important because it would take several lifetimes to learn through trial and error how to distinguish between speech and nonspeech sounds.

Even more sophisticated forms of prewired knowledge are referred to as intermodal matching or cross-modal fluency. Meltzoff and Moore (1977) first described the ability of 2 to 3-week-old infants to imitate human facial expressions. This capacity requires that infants match a visual schema of the facial expression with the proprioceptive–tactile schema of the act of producing the facial expression. This visual–proprioceptive cross-modal translation has been replicated in infants of 36 hours old (Field et al. 1982). In another study, 1-month-old infants were given either a smooth or rough pacifier. When shown both pacifiers, infants looked preferentially at the pacifier they had mouthed but had never seen before (Meltzoff and Borton 1979). This tactile–visual matching seems to be innate rather than learned, although the debate still lingers (Maurer et al. 1999). Finally, infants are able to match the intensity of events across modalities. For example, infants can indicate that a light of a certain brightness is comparable to a sound of certain loudness (Lewkowicz and Turkewitz 1989). Visual–tactile matching is facilitated preferentially by two-dimensional rather than three-dimensional representations (Strer and Molina 1993).

Four-month-old infants are also capable of matching faces and voices when presented with an adult’s or child’s face or voice (Bahrick et al. 1998). Stern has emphasized the importance of cross-modal fluency for interactional synchrony and for early self–other differentiation in human infants.

Although there has been great interest in the innate knowledge and learning capacities of newborns, it is important to remember that demonstrations of these capacities require setting up careful experimental conditions and conducting frequent trials that generate only a small amount of usable data. In fact, newborns have important limitations in their cognitive capacities, which become substantially more sophisticated beyond the first 2 months of life.

For experience to be significant in the development of individual infants, they must have some ability to form representations of experience that they carry forward. Developmental research on memory has demonstrated that infants, from birth, are capable of perceiving and recalling experiences in the form of behavioral, perceptual, emotional, and somatosensory modes, although remembering does not involve any subjective sense of recall (Bauer 1996). This implicit memory does not require conscious processing during encoding or retrieval (Squire et al. 1993). Implicit memory must rely on brain structures present and functioning at birth, such as the amygdala, basal ganglia, motor, and perceptual cortices. As already described, the infant’s mind is able to detect similarities and differences across experiences and modalities, and thus has a process for making generalizations. These generalizations represent the sum of what the infant has experienced and also determine the infant’s anticipations of what will come next (Siegel 2001).

These memories or representations are encoded not in the temporal cortex but in the neural circuits directly involved in behavior, emotion, and image. We will elaborate further on these processes in subsequent sections.

Emotional Development

Most observers agree that newborns exhibit two major forms of emotional expression: distress and contentment. Nevertheless, Lewis (1994) has pointed out that the expression of interest also seems to be present at birth. He has proposed a model of differentiation of emotional expressions in which the three major emotional states, contentment, interest, and distress, are present in the first 2 months of life and later differentiate into more specific emotional states. All of the studies of early emotions rely on infants’ emotional experience based on facial expressions of emotion and crying; still, most investigators believe that facial expressions are reasonable indices of emotional experience (Lewis 1994).

Communicative Development

Biological, cognitive, and emotional development in infants during the first 2 months have implications for the infants’ communicative behaviors. A wide variety of spontaneous behaviors in the neonate, including diffuse motility, crying, smiling, startles, and mouthing movements, guarantee that the infant has an impact in the environment. The recurrence
of these behaviors during the different states of sleep and wakefulness, providing periodic opportunities to relate to significant others. As infants become better organized and more rhythmically regulated during the first 2 months, they also probably exert a more systematic impact on caregivers, who are highly attuned to interpreting who their infants are and what their infants’ behavior means (Zeanah and Anders 1987). In fact, interaction with adult caregivers is frequently initiated by infants through enactment of simple, recurring behaviors that stimulate affiliative responses by adult caregivers.

Infants prefer human faces and voices to inanimate objects or to nonspeech sounds. Long before language symbols are available to infants, they are communicating interactively through crying, quieting, cuddling, looking, and occasional vocalizations. Caregivers, whose attributional processes are highly attuned to infant behaviors, respond to these communications and imbue them with elaborate meanings (Zeanah and Anders 1987).

**Social Development**

Infants are wonderful projective stimuli. They elicit interest and responses from caregivers, who unconsciously change their behaviors to optimize interaction with the infants (Stern 1985). Facial expressions are exaggerated in time and space. Speech is modified by amplified syntax, short length of utterance, nonsense sounds, and transformations of consonants (i.e., motherese). Vocal pitch is exaggerated and sound intensity is varied more dramatically when caregivers communicate with infants than when they speak with adults. The speed of speech is generally slowed down, with brief eruptions of speeded-up utterances. Gaze is maintained by adult caregivers with infants for much longer periods than with adults. These changes in adult behavior are testimony to the socially evocative power of human infants.

Klaus and Kennell (1976) first popularized the term “bonding” to describe the parents’ emotional ties to their newborn infants. Observations of newborns provide underpinnings of the argument that the first few hours after birth constituted a “sensitive period” for facilitating parental attachment to their children. These observations include the following: (1) a newborn left on its mother’s abdomen will crawl to her breast, turn its head, find the nipple, and begin suckling within the first hour of life (Varendi et al. 1994); (2) a mother’s ability to thermoregulate the baby’s body temperature is as efficient as a high-tech heating device (Christensson et al. 1992); and (3) an infant cries less on its mother’s chest than when being dried, wrapped, and placed in a bassinet (Christensson et al. 1995). Providing or preventing an opportunity for parents to have intimate physical contact with their newborns has putative long-term effects on the parent–infant relationship. Although their assertions contributed to a useful deinstitutionalization of the childbirth experience, they probably overstated the importance of the immediate period after birth and oversimplified attachment by dichotomizing it as present or absent. Early contact between parents and their newborns should be regarded as potentially helpful rather than essential.

Several studies have investigated the onset of parents’ reported feelings of affection for their infants, although methodological problems make generalization difficult. There appear to be wide variations in onset of affection from the first trimester of pregnancy to several weeks after birth. The clinical significance of these findings is not established, although it is clear that most of the US mothers report feeling as if they love and have a relationship with their infants within the first several weeks after birth (Zeanah et al. 1990). There is also preliminary evidence that breast-feeding may facilitate these feelings, perhaps mediated by the release of oxytocin after the mother’s breast is stimulated by the infant’s lips (Nissen et al. 1992).

**Summary of Development in the First 2 Months**

In contrast to earlier theories of development that held that the human newborn was disorganized, passive, reactive, or withdrawn, research on newborn behavior suggests a radically different view. Biological, cognitive, communicative, emotional, and social capacities, which are functionally integrated, enable infants to seek stimulation actively and to regulate their own behavior through interactions with the environment. The psychobiological endowment of infants at birth includes prewired knowledge of the world, such as cross-modal fluency, as well as a remarkable ability to detect and to remember invariant aspects of experiences. These capacities make the infant in the first 2 months of life a far more sophisticated social partner than most widely quoted developmental theories have recognized.

**2- to 3-Month Transition**

The first significant developmental transition occurs at about 2 to 3 months of age. A significant convergence of researchers, theoreticians, and clinicians have noted dramatic qualitative changes in infants that occur at this time. Stern (1985) has pointed out that parents also frequently remark about the qualitative change that occurs at this time because their infants become more focused, better organized, more communicative, and more enjoyable social partners.

**Biological–Neurological Development**

Development of the central nervous system at the time of the 2- to 3-month transition is beginning to be studied. Brain growth which continues at a rapid pace after birth, results from growth of neurons and their connections. Growth of synapses in the cortex enters its most rapid phase from about 2 to 6 months of age. Again, synaptogenesis appears in association with functional development. For example, synapse formation in the auditory cortex precedes synaptic formation in Wernicke’s area, which, in turn, precedes formation in Broca’s area (Huttenlocher 1999). Midbrain–cortical visual pathways become myelinated at this time (Ceaser 1993).

Functional changes in the brain are also apparent after this transition at 2 months. Local rates of glucose metabolism, as determined by PET, are believed to represent an important window into brain functioning. Maturation of patterns of glucose metabolism is apparent for the first time in large parietal, occipital, and temporal areas after the 2- to 3-month transition (Chugani 1994), coinciding with improved visuospatial and visuomotor integration, the disappearance or reorganization of brainstem reflex behaviors, and evidence of increasing cortical contribution to the Electroencephalogram (EEG). In addition, electrophysiological research corroborates functional changes (Emde et al. 1976). Although we have not yet moved beyond global correlations between developments at the level of brain
functioning and newly appearing behavioral capacities, this is an area in which rapid progress may be anticipated within the next few years. At present, a host of changes in infant behavior and capacities at 2 to 3 months of age have biological correlates that are only partially elucidated.

One of the hallmarks of the 2- to 3-month transition is the social smile. Interestingly, evidence suggests significant genetic contributions to the onset of social smiling. Onset of social smiling is better predicted by the date of the last menstrual period than by the time elapsed since birth (Hofer 1981). Furthermore, monozygotic twins are more concordant for onset of social smiling than are dizygotic twins (Freedman 1974).

Another important maturational development for most infants is that the diurnal organization of sleep–wake cycles begins to appear at this time (Anders et al. 1983, 1985). Infants begin spending more of their time sleeping at night and having longer periods of wakefulness during daylight hours, probably as a result of maturation of internal pacemakers (Anders and Zeana 1985).

Most investigators believe that after the 2- to 3-month transition, behaviors reflecting temperamental dispositions are apparent. All of the major theories of temperament endorse the idea that temperament is rooted in biological differences (Goldsmith et al. 1987). The most influential view has been that of Thomas et al. (1968) in the New York Longitudinal Study. They viewed temperament as a child’s behavioral style, the "how" of behavior as opposed to its content or motivation, and they included dimensions such as activity level, intensity of emotional expression, adaptability to changes in routine, and the tendency to approach or avoid in novel situations.

A major advance in temperament research in the past two decades has been increased emphasis on behavioral assessment of temperament rather than parental report. Perhaps the most widely used laboratory assessment for tapping a broad range of temperamental dispositions for infants in this age range is the Laboratory Temperament Assessment Battery (Lab-TAB) procedure (Goldsmith et al. 1987). This allows for operationalization and standardized assessment of a number of important domains, including assessments of attention, inhibitory control, and positive and negative expression of emotions, among others.

Following the 2- to 3-month transition, temperamental differences begin to emerge more clearly than they had in the first two months (Rothbart 1981, Rothbart and Derryberry 1981). Rothbart’s model of temperament derives from current empirical work in neuroscience, particularly the work of Davis (1992) and LeDoux (1987), to describe the neural systems involved in temperamental “fear.” Also, she has used the neuroscience work of Posner (Posner and Peterson 1990), Tucker (Tucker et al. 1995) and others to describe the neural systems relevant to the development of attentional and cognitive systems involved in the regulation of fear, as well as describing constructs such as surgency (preferring high-intensity stimulation, extraverted, active, positive affect), negative affectivity (disposed towards anxious or irritable behavior), and effortful control (well regulated attention, prefers low-intensity stimulation), and orienting sensitivity. One of the unique aspects of Rothbart’s model is that temperament is not only a biological given present at birth but also as a developing individual difference that emerges across the period of early childhood. Individual differences in reactivity and in the processes involved in the control of such reactivity both fall under the purview of temperament (Rothbart and Bates 1998).

Cognitive Development

At 2 to 3 months after birth, infants develop greatly enhanced cognitive capacities across a number of different types of learning. Infants demonstrate enhanced classical conditioning, operant conditioning, and habituation at about this time. In general, infants become more interested in a wider range of the world around them. Piaget (1952) designated this period of focus as that of secondary circular reactions as the infant behaves to make interesting spectacles last.

Emotional Development

Further elaboration and development of the basic emotions of contentment, distress, and interest, which may be reliably observed in the first 2 months of life, begin after the transition at 2 to 3 months. By the time infants have reached 6 months of age, they exhibit a differentiation of contentment into joy and contentment, of interest into surprise and interest, and of distress into sadness, disgust, and anger (Lewis 1994).

Lewis (1994) has provided a timetable for the emergence of discrete emotional expression. Joy appears soon after the 2- to 3-month transition and is often elicited by familiar faces, voices, or events. Sadness appears at about the same time and has been reliably elicited in middle-class US infants when their mothers stop interacting with them. Disgust appears for the first time also, often in the context of an unpleasant new taste. As with the ability to demonstrate emotions, infants also acquire the ability to perceive emotions in a developmental fashion, relying initially on multimodally presented information, and then shifting to vocal recognition, and then to facial expressions alone (Walker-Andrews 1997). Context also determines the infants’ ability to recognize emotions, with infants as young as 3.5 months able to recognize happy and sad expressions in their own mothers but not in unfamiliar women (Kahana-Kalman and Walker-Andrews 2001).

Anger is clearly evident somewhat late, perhaps between 4 and 6 months of age, although it has been demonstrated as early as 2 months in specially designed experimental situations (Lewis et al. 1990). Because it includes a response designed to overcome some obstacle to a goal, the emergence of anger must be closely tied to the cognitive capacity needed to appreciate the relationship of a means to an end (Lewis 1994). This suggests that at least a limited form of means-end differentiation must be available to human infants even before 7 months of age.

During this period, the infant is also learning strategies from caretakers about regulating emotion. Emotion-regulation, defined as an individual’s attempt to monitor, evaluate, and modify their internal emotional reactions (Thompson 1994), and emotion-related behavior regulation (Eisenberg 1997), defined as the modulation of the overt expression of emotion, serve as regulatory attempts to monitor internal, emotional states and external, emotional displays in a goal-directed attempt to regulate response. Because of the relational context of emotion expression in early infancy, emotional regulation at this point in time is both a within-the-infant and a relational property.
Communicative Development

Communicative behavior of infants changes after the 2- to 3-month transition. Infant vocalizations become more clearly social as infants begin to react to vocalizations from others and to coo responsively. Patterns of turn-taking in vocalizations begin to appear at this time, suggesting far greater appreciation by infants of the behavior of their interactive partners.

Expressive communication at 2 to 3 months includes production of several different vowel sounds (e.g., ah, eh, uh) as well as some simple mutual imitation. Coos, squeals, and screams appear at about 2 months, followed by consonants at 4–6 months, as infants begin to babble (canonical babbling) using repetitive syllable sequences, such as da-da-da (McCormick 1984).

Advances in receptive language are apparent after the 2- to 3-month transition, as well. In addition to the enhanced ability to take into account the behavior of others, infants begin to localize the source of voice sounds and noisemakers. They attend and respond differently to different affects in caregivers, such as anger and playfulness (McCormick 1984). At this early age, the infants’ perceptual abilities for speech are impressive. They can already recognize the same speech sound when spoken by different speakers and at different rates (Jusczyk 1999).

These enhanced receptive and expressive communicative capacities are central components of a blossoming of social behavior that appears concurrently. Essentially, these changes in communicative behavior make possible a qualitative advance in infants’ abilities as social partners.

Social Development

Enhanced eye-to-eye contact, diminished crying, more sustained wakefulness, periods of quiet alertness, and blossoming of the social smile all contribute to a sense of the infant as a more playful and engaging social partner after the 2- to 3-month transition. Therefore, it is not surprising that a great deal of attention has been paid to infants’ social behavior in the period from 2 to 7 months. Individual differences in infant–parent interactive behaviors, as measured by features such as matching emotional states, synchrony, reciprocity, and turn taking, have been related to infants’ cognitive competence (Barnard et al. 1989), emotion regulation (Lyons-Ruth and Zeanah 1993), language development (McCormick 1984), and sense of self (Stern 1985).

Infants who are interacting with their caregivers between 2 and 7 months engage in alternating periods of engagement and disengagement, or time-outs. The interactive pattern of a dyad may be thought of as a mutual feedback system in which each partner’s behavior affects the other’s in ongoing transactions over time (Beebe et al. 1985, Cohn and Tronick 1988). Infants are more likely to respond to changes in their mothers’ behaviors if mothers are more responsive to changes in their behavior (Cohn and Tronick 1988) and able to interpret their infants’ emotions accurately.

What sustains play periods or social interaction for infants at this age is maintaining the level of stimulation within some optimal range. If caregivers provide too little feedback, infants lose interest and turn their attention elsewhere. If caregivers are too stimulating, infants avert their gaze or otherwise interrupt or even terminate the interaction until the stimulation is reduced to a level that they can tolerate.

Although much of the literature on infant–parent interaction has emphasized matching affective states, infants and their caregivers actually spend little time in matching states, even when observed in situations designed to maximize opportunities for interaction. This observation led Tronick and Cohn (1989) to speculate that infants’ coping strategies are challenged by their efforts to effect repair of mismatching affective states and interactive errors. These efforts would then stimulate efforts to attain reparation and effectance. Some studies have demonstrated links between individual differences in infants’ emotion regulation efforts at this age and subsequent development. For example, infants who used more positive efforts to elicit responsiveness from their mothers (when the mothers had been instructed to refrain from responding) were more likely to be securely attached at 1 year of age (Cohn et al. 1991). Not surprisingly, infants who were more positive also had mothers who were more sensitive in their caregiving responses (Kogan and Carter 1996).

Depressed mothers often are unable to match positive affective displays with their infants. Presumably, this leads their infants to display more negative and less positive affect (Cohn et al. 1986). In addition, this pattern generalizes to nondepressed strangers (Field et al. 1988), but not to nondepressed fathers (Hossain et al. 1994). Infants of depressed mothers also demonstrate atypical right frontal brain electrical activity, known as right frontal EEG asymmetry, as early as 1 month of age (Dawson et al. 1999, Jones et al. 1997).

Repeated patterns of social interaction are remembered and even anticipated by infants between 2 and 7 months. If mothers are instructed not to respond to infant displays by keeping their faces “still,” infants exhibit negative affect and behavioral dysregulation (Cohn and Tronick 1988). These early interactions also seem to be internalized by the infants and lead to later positive reciprocity. An observation of maternal sensitivity behavior at 3 months correlated with infants’ positive mood, social and play behavior, and visual contact. These findings were replicated at 12 months. Statistical analysis showed that infant behavior at 3 months of age contributed to later maternal sensitive behavior (Kiviärvi et al. 2001). The nature of these early social expectations is believed to have great importance in influencing the way infants anticipate and experience intimacy in later relationships (Stern 1985).

Summary of the 2- to 3-Month Transition

Dramatic changes in developmental capacities across a number of domains appear between 2 and 3 months after birth, changing both infants’ behavior and the behavior of caregiving adults. All of these changes enhance infants’ appeal to others as a more responsive and enjoyable social partner. The nature of caregivers’ responsiveness to infants is associated with relationship characteristics that probably have far-reaching implications for infant development. Infants’ efforts at adaptation within the goal-correcting system of interaction with their primary caregivers provide an early feel for what it is like to be with another in an intimate relationship.
7- to 9-Month Transition
At 7 to 9 months, another major developmental transition occurs. This has been one of the best studied transitions from biological, cognitive, communicative, and socioemotional perspectives. Emde (1984) has termed this shift the “onset of focused attachment,” and Stern (1985) has termed it “the discovery of intersubjectivity.” Both of these conceptualizations call attention to the enhanced importance of subjective experience for infants that develops at this time.

Biological–Neurological Development
Evidence for changes in brain development at this time is extensive. As Fischer and Rose (1994) have pointed out, these include changes in electroencephalographic frequency, power, and coherence; changes in patterns of glucose metabolism documented throughout PET techniques; and a spurt in head circumference and brain growth (Bell and Fox 1992, Chugani and Phelps 1986, Epstein 1974, Fischer 1987). Increased glucose requirements also coincide with the expansion of dendritic fields and the increased capillary density observed in the frontal cortex during this time (Diemer 1968, Schade and van Groenigen 1961). Research also has demonstrated that selected portions of the limbic system are myelinated at this time (Ceaser 1993). These documented changes are all compatible with a hypothesized qualitative change in central nervous system functioning that may be associated with other qualitative changes in motor, cognitive, emotional, and social domains of development.

Fischer and Rose (1994) have suggested that biological changes along with other developmental advances at these times must include connections between the frontal cortex and other regions because more sophisticated cognitive and communicative skills require coordination of components, which is a frontal region activity. In keeping with this reasoning, a new rise in glucose metabolism in the frontal lobes occurs at the time of the 7- to 9-month transition (Chugani 1994). Also, Bell and Fox (1992) demonstrated that both EEG frequency and coherence change at this time of transition, implying that they reflect improved inhibitory control of the prefrontal cortex and enhanced associative pathway links. Having more sophisticated coordination of pathways probably makes possible the qualitatively different behavioral advances that are apparent at this time.

With regard to temperament, individual differences in the second half of the first year and first half of the second year may be a bit more stable than in the first 6 months of life, although the absence of an agreed-upon “gold standard” assessment procedure has limited interpretability of findings. The general trend is for parental convergence about temperamental differences to increase during this time, although lack of convergence between parental report and observer ratings of temperament remains a formidable challenge (Seifer et al. 1994).

Cognitive Development
In the cognitive realm, dramatic advances are apparent. Infants are now able to use one scheme as a means of obtaining another scheme that is the desired goal. For example, infants know that they can pull a string to reach an attractive toy to which the string is attached. This means-end behavior is the prototype of all later problem-solving behavior. In addition, infants demonstrate object permanence; that is, infants purposefully remove a cloth covering a hidden object that seems to have disappeared under it. This suggests that infants possess an enhanced ability to retain a mental image of the absent object.

This enhanced capacity has been used to explain the development of stranger reaction and separation protest, which appear for the first time after the 7- to 9-month transition. Infants begin to protest separations from their primary caregivers and react with increased wariness or outright distress when approached by unfamiliar adults.

Also, in the cognitive realm, infants begin for the first time to explore novel properties of objects and to pursue novelty for its own sake. The notions of causality advance, and infants at this age develop a clearer understanding of the independence of objects and that these objects carry with them their own properties. Infants also begin to experiment with different ways of accomplishing goals when their efforts are thwarted (Piaget 1952).

A tendency for infants to explore the unfamiliar and to attempt to master challenges through repeated practice emerges in the latter part of the first year and has been termed “mastery motivation.” Mastery behaviors are believed to reflect an innate motivational system in human infants. As assessed in the laboratory, mastery has been shown to be stable over months and to be predictive of subsequent cognitive performance (Messer et al. 1986). In addition, mastery behavior is related to maternal feedback and control at 24 months (Kelley et al. 2000). Mastery appears to represent early indicators of competence, although most efforts to capture these behaviors in the laboratory have been focused on cognitive rather than social competence.

Progress toward symbolic or pretend play begins to emerge after the 7- to 9-month transition, although true pretend play does not appear until after the 18- to 20-month transition. Whereas before 9 months, infants’ play with toys consists largely of banging, mouthing, or visually inspecting them, by about 12 months functional play appears. At this age, infants may hold a telephone receiver properly, then let it go, or hug a baby doll. Over the course of the next 6 months, other-directed play generally increases until true pretend play emerges.

Perhaps the most important cognitive development in terms of its social and emotional implications for the infant is the discovery of intersubjectivity (Trevarthen 1979). This refers to a variety of changes in infant behavior that seem to indicate that infants now understand that their own inner experience, that is, their thoughts, feelings, and desires, can be appreciated by and shared with others. The ability to share thoughts and feelings with others represents a monumental discovery for infants, with far-reaching implications for the development of empathy and the subjective experience of intimacy.

Emotional Development
One of the more important clinical and developmental phenomena that intersubjectivity makes possible is “affect attunement” (Stern 1985). Affect attunement between mother and infant involves an emotional interchange in which the mother matches her behavior to the infant’s behavior. This matching is not imitative; rather, it involves some aspect of an internal feeling state that is shared. Single occurrences
of affect attunement appear at 2 to 4 months and become more common than imitation by 6 months, and eventually the dominant mode of relating by 8 months (Jonsson et al. 2001). Affect attunement appears to be an essential ingredient of empathy, intimacy, mirroring, and other clinical phenomena.

Emotions begin to be used instrumentally for the first time after the 7- to 9-month transition (Emde 1984). Smiling and pouting expressions mark infants’ efforts to get their own way. For the first time, anger is often purposefully directed toward another person. Parental report studies have suggested that parents as well as observers note that infants begin to use affects as a means to an end toward the latter half of the first year (Klinnert et al. 1983).

Infants also begin to detect and share affective states with their social partners. Social referencing describes infants’ use of cues from others to resolve affective uncertainty (Moses et al. 2001). If a mother and her 1-year-old are in a playroom and a noisy and flashing robot advances toward the infant, the infant looks at the mother’s face. If the mother smiles encouragingly, the child is likely to smile toward the infant, the infant looks at the mother’s face. If the mother looks frightened, on the other hand, the infant is likely to cry or approach the caregiver for comfort. Infants are just as likely to reference their fathers as their mothers (Hirshberg and Svejda 1990), and they also adapt different strategies with each parent (Bridges and Grohnick 1998). There is additional evidence that infants also use fearful maternal vocalizations even when unaccompanied by matching facial features (Mumme et al. 1996).

Mahler et al. (1975) suggested that exuberance and joy are the dominant emotions around 1 year of age, noting that infants at this age also demonstrate a relative impatience to frustration. These observations have not yet been subjected to any attempt at empirical confirmation.

Communicative Development

The importance of intersubjectivity for communicative development cannot be overstated. After the 7- to 9-month transition, infants begin to behave not only as if they understand others but also as if they anticipate that others will understand them. Infants younger than 7 months may reach for desired objects, but they do not check back to the caregiver’s face in an appeal for help. After 9 months, infants behave as if they attribute to the other person comprehension of their own intention and the capacity to satisfy their intention. This builds on their capacity of parsing dynamic actions into initiation and completion of events (Baldwin et al. 2001).

The emergence of intentional communication is one of the hallmarks of the 7- to 9-month transition, with major implications for the infant's new appreciation of both self and other. In contrast to Mahler et al. (1975), who viewed infants at this age as only beginning to emerge from symbiotic unity with their mothers, Stern (1985) has argued convincingly that it is only after infants develop intersubjectivity that they can even conceive of the kind of unity that Mahler presupposes to be present at birth.

Advances in symbolic functioning after the 7- to 9-month transition also have communicative implications. Infants understand by 8 to 10 months that a word is agreed upon to designate a specific object, a specific phonetic form for a specific object. By 1 year of age, infants may have an expressive vocabulary of a few words, although getting an appreciation of language dominates in interactions until the latter part of the second year (McCormick 1984). Language development does not occur in isolation, it requires effort and engagement (Bloom 1998). For example, maternal responsiveness at age 9 and 13 months predicted the timing of children’s achieving language milestones over and above children’s observed behaviors (Tamis-LeMonda et al. 2001).

Previous exposure to language also affects how language continues to be perceived. For example, newborns and toddlers less than 8 months of age can discriminate among all the phonetic units used in the world’s languages regardless of the language environment in which they will be raised. However, previous exposure to a specific language affects future perception of linguistic phonemes. At 7 months of age, Japanese infants equally discriminate between American English “r” and “l,” but by 10 months of age, they have lost this ability (Kuhl 1999). Also, at 6 months of age, infants do not show preference for native speakers or native stress patterns, while they do so at 9 months of age.

Social Development

Of course, biological, cognitive, emotional, and communicative developments at the 7- to 9-month transition have major implications for infants’ social development. Stern (1985) has emphasized that what infants discover at the 7- to 9-month transition is that their own inner subjective experiences may be shared with someone else. Intentional communications via gestures that convey “I want a cookie,” affective sharing that conveys “This is exciting!” or joint referencing that conveys “Look at this toy” are all evidence of that intersubjectivity. When this occurs, interpersonal relatedness has moved in part from overt actions and responses to internal subjective states lying behind the actual behaviors. Stern (1985) has emphasized that infants not only feel different to others but also experience others differently. At this point, infants not only experience caregiver empathy through overt behavioral responses but also directly experience the subjective empathic process of which these responses are only a part.

There is also another monumentally important social development at this time—the infant “falls in love.” Although the attachment relationship between the caregiver and the infant begins to develop at birth, it becomes increasingly focused during the latter half of the first year. Attachment describes a tendency for human infants to seek comfort, support, nurturance and protection from one or more discriminated caregivers. The tendency for selective seeking of comfort is not apparent at birth, however. Following a period of sociability and comfort with a wide range of adult caregivers during the first 6 months, two new infant behaviors appear: stranger wariness and separation protest, both at about 7 to 9 months of age. Stranger wariness describes an apparent discomfort with unfamiliar adults and selectively turning to those they know and trust for comfort. Separation protest refers to the infant’s new tendency to protest separation from familiar caregivers. Although individual differences in the intensity and expression of these behaviors is clear, they may be considered virtually ubiquitous. When these behaviors appear, the infant is said to be attached to one or more caregivers.
Under species-typical rearing conditions, all infants become attached to caregivers. Research has demonstrated clearly that the quality of infants’ attachments to one or more caregivers is predictive of subsequent psychosocial adaptation. By the time the infant is 1 year old, the quality of the attachment relationship to a particular caregiver can be measured categorically. A laboratory procedure known as the Strange Situation Procedure (SSP) involves observing how 11-month transition to 20-month old infants organize their behavior around attachment figures when they are mildly stressed by being in a strange room, encountering an unfamiliar adult, and being left briefly by their attachment figure (Ainsworth et al. 1978). The most important parts of the procedure from the standpoint of classifying the infant’s attachment relationship are the two reunion episodes between infant and caregiver after separation. Qualitatively different patterns of infant to caregiver attachment have, as assessed by the (SSP), have been replicated in studies conducted throughout the world. These patterns include secure attachment, and several forms of insecure attachment, including avoidant, resistant, and disorganized attachment. Table 8–4 provides a list and description of infant attachment patterns.

Caregivers support infant attachment through two forms of emotional and behavioral responses. Secure base behaviors by the caregivers support the infant’s moving out into the world to explore. Safe haven behaviors by the caregivers support the infant’s need to return for comfort, support, and nurturance. Securely attached infants demonstrate a fluid and responsive balance between these two tendencies. Later in development, this balance between exploration and attachment becomes a balance between the individuals’ need to balance independent functioning with a need to rely on others.

Infants who lack a coherent strategy of emotional and behavioral regulation during reunion episodes are classified as disorganized. Caregiving behavior predictive of this classification is characterized as being either frightened or frightening. That is, the caregiver behaves in ways that make the infant feel afraid of or fearful about the caregiver’s emotional well-being. In addition, broader indices of caregivers’ disrupted affective communication with their young children, including high levels of expressed emotion, have been linked to disorganized attachment in young children.

Attachment classifications are not within-child traits (as temperament is believed to be); instead, these classifications summarize salient features of the relationship pattern between an infant and a particular caregiver. The clearest evidence for this is that infants’ attachment classifications with different caregivers may be different (Fox et al. 1991). Moreover, Steele and associates (1993) identified differential characteristics in mothers and in fathers prenatally that were predictive of mother–infant and father–infant attachment measured more than a year later.

Secure attachment is perhaps best considered as a protective factor against the development of psychopathology. For example, infants classified as securely attached to their primary caregivers at 12 and 18 months are more developing more favorably emotionally and behaviorally in preschool, school age, and adolescence (Weinfield et al. 2000). At present, one of the best indicators in infancy of later adaptation is the security of the infant’s attachment classification to the primary caregiver as measured by the Strange Situation Procedure.

In terms of risk for psychopathology, the strongest links have been demonstrated between disorganized attachment and psychopathology rather than any other types of insecure attachment. Disorganized attachment has been demonstrated to predict a variety of externalizing and internalizing problems concurrently and in later childhood and adolescence. Still, attachment relationship experiences are more clearly related to psychopathology when considered in the context of other risk factors. What is far less clear, are the mechanisms involved linking attachment relationship experiences and psychopathology.

After 7 to 9 months of age, almost all infants will demonstrate discriminated attachments to one or more trusted adults. For infants raised in extremely adverse caregiving environments, however, such as in severely neglectful homes or in institutions, attachment may be seriously compromised or even absent (Zeanah et al. 2004, Zeanah et al. 2005). Reactive Attachment Disorder (RAD) describes a constellation of aberrant attachment behaviors and other social behavioral anomalies that are believed to result from sexual neglect and deprivation. Two clinical patterns have been described: an emotionally withdrawn/inhibited pattern and an indiscriminately social/disinhibited pattern. In the

In terms of risk for psychopathology, the strongest links have been demonstrated between disorganized attachment and psychopathology rather than any other types of insecure attachment. Disorganized attachment has been demonstrated to predict a variety of externalizing and internalizing problems concurrently and in later childhood and adolescence. Still, attachment relationship experiences are more clearly related to psychopathology when considered in the context of other risk factors. What is far less clear, are the mechanisms involved linking attachment relationship experiences and psychopathology.

After 7 to 9 months of age, almost all infants will demonstrate discriminated attachments to one or more trusted adults. For infants raised in extremely adverse caregiving environments, however, such as in severely neglectful homes or in institutions, attachment may be seriously compromised or even absent (Zeanah et al. 2004, Zeanah et al. 2005). Reactive Attachment Disorder (RAD) describes a constellation of aberrant attachment behaviors and other social behavioral anomalies that are believed to result from sexual neglect and deprivation. Two clinical patterns have been described: an emotionally withdrawn/inhibited pattern and an indiscriminately social/disinhibited pattern. In the
emotionally withdrawn/inhibited pattern the child exhibits limited or absent initiation or response to social interactions with caregivers and aberrant social behaviors, such as inhibited, hypervigilant, or highly ambivalent reactions. This type seems to be equivalent to the absence of a discriminated attachment figure. In the indiscriminate pattern, the child exhibits lack of expected selectivity in seeking comfort, support and nurturance, with lack of social reticence with unfamiliar adults and a willingness to “go off” with strangers. This pattern often remains even after the child develops one or more discriminated attachments.

Summary of the 7- to 9-month Transition
Infants emerge from this period of developmental transformation quite differently than when they entered it—in cognitive, communicative, emotional, and social terms. After the 7- to 9-month transition, infants act as if they understand that their thoughts, feelings, and actions can be understood by another person, and they have strong preferences for caregivers with whom they have established relationships. The dual capacities for intersubjectivity and focused attachment underlie the specific changes in capacities that develop at this time. These changes continue to develop and to be refined throughout the next year, but their appearance for the first time after the 7- to 9-month transition makes infants at this age qualitatively different social experiencers and agents (Stern 1985). Under usual circumstances, after 7 to 9 months, infants have developed a strong preference for turning to a relatively small number of caregiving adults for nurturance and comfort. By having their caregiver function as a secure base from which to explore their environment and other relationships, and a safe haven to which they can return during periods of stress, they can use more sophisticated motor capacities for independent locomotion to explore the world exuberantly.

18- to 20-Month Transition
The final transition period of major reorganization in infancy occurs at age 18- to 20-months. Although this transition is marked dramatically by the appearance of language, it is actually the qualitative change in symbolic representation that underlies the child’s remarkable advances in language, cognition, affect, and social functioning at this age. These advances predate the evolution of infants’ moral development, which burgeons after the 18- to 20-month transition. After this transition, much of what follows in the third year involves further elaboration, refinement, and consolidation of the functions that emerge during the transition.

Biological–Neurological Development
Much remains to be learned about specific dimensions of brain development at 18 months and about the relationships between this development and changes in behavior at this time. Evidence suggests that there are important associations between changes in central nervous system structure and function and the spurt in capacities noted to appear in other domains of development across the period of reorganization.

One of the important spurts of brain growth in the first 2 years of life occurs at about 10 to 20 months and is due to myelination and to synaptic growth and pruning. Density of dendritic spines, which represent sites of synaptic contact, decreases postnatally and almost reaches adult levels by 21 months of age (Huttenlocher 1994). Myelination of structures associated with language occurs at 18 months (Chugani 1994). Associated behavioral changes need to be studied in relation to these anatomical developments. Functional changes are apparent as well. Although local cerebral metabolic rates for glucose in infants qualitatively resemble those of adults by 1 year of age, they typically reach levels comparable to those of adults in the second year (Chugani 1994).

Discontinuities in event-related potentials between 13 and 20 months have been documented in association with processing of language. Specifically, by studying differential responses of brain electrical activity to comprehended unknown words, investigators have demonstrated that different parts of the brain are involved in language comprehension (Mills et al. 1994). Whereas diffuse patterns of activity were widely distributed over the anterior and posterior parts of both hemispheres before 18 months, by 20 months they had become more localized to temporal and parietal regions of the left hemisphere.

These data suggest increasing lateral and anterior–posterior specialization of brain systems responsible for language comprehension at the 18- to 20-month transition. In fact, individual differences in language competence have been associated with the degree of specialization of brain function (Mills et al. 1994).

In the realm of temperament, behavioral inhibition is a trait that has been reliably identified after the 18- to 20-month transition. Kagan et al. (1987) have suggested that behavioral inhibition to the unfamiliar characterizes about 10% of middle-class white 2-year-olds and is counterbalanced by a roughly equal number of children deemed uninhibited. Descriptively, uninhibited infants strongly avoid novel stimuli. Kagan et al. (1987) have suggested that despite the poles of inhibited and uninhibited, behavioral reactivity in the face of novelty does not represent a continuum. Instead, they believe that behaviorally inhibited children represent a qualitatively different group. In support of this assertion, they have demonstrated stability of the trait for 4 years and associated it with physiological activation of the hypothalamic–pituitary–adrenal axis, the reticular activating system, and the sympathetic arm of the autonomic nervous system (Kagan et al. ). In addition, infants who remained continuously inhibited displayed right frontal asymmetry as early as 9 months of age (Fox et al. 2001), which in turn, is especially predictive of social wariness at age 4 years (Henderson et al. 2001). Behavioral inhibition is associated with increased incidence of social withdrawal and internalizing behaviors in early and middle childhood and possibly predisposes to anxiety disorders in adolescence. A number of studies have shown that inhibited children are more likely than their uninhibited peers to display symptoms of anxiety (Biederman et al. 1993, Hirshfeld et al. 1992, Schwartz et al. ). Thus, behavioral inhibition is a heritable trait that is mediated through central and peripheral nervous systems and predisposes infants to anxious and inhibited behavior in a variety of novel contexts.

Cognitive Development
A qualitative advance in symbolic representation at 18 to 20 months is believed to be the central cognitive development occurring at this time. More sophisticated symbolic
representation makes possible significant advances in infants’ understanding of causality, including the ability to infer causes based on observed effects and to anticipate effects based on their actions. They are also able to remember specific past events and sequences even when no sign of the event or sequence remains. This capacity allows the infant access to two versions of the same reality: a representation of the original act as performed by the other and a representation of their own anticipated performance of the act. This seems to require some representation of the self as an objective entity.

In fact, Lewis and Brooks-Gunn (1979) and Kagan (1981) have provided evidence of the emergence of an objective self at 18 months. Experimental studies have demonstrated toddlers’ clear facial recognition of themselves in mirrors, in still photographs, and in videotapes. In addition, self-awareness has been demonstrated by self-descriptive utterances, by a variety of gestural directives, and by emotional reactions to success or failure. Personal pronouns begin to be used at this time. Gender identity appears to consolidate at this point, although it is not until about age 5 years that children attain gender constancy wherein they recognize gender is an immutable characteristic of the individual (Gouze and Nadelman 1980).

A further dramatic implication of symbolic representation occurs in the realm of pretend play. Whereas younger toddlers’ play is generally self-directed, by the time a child is 18 months, the play has become progressively more other directed and is more sustained. True pretend play emerges at this time and becomes progressively richer and more complex. The importance of all these advances is that infants can, for the first time, entertain and maintain a formed wish of how they would like reality to be, even if this is different from fact (Stern 1985). Internal experience of social interactions now includes wishes that involve past memories, present realities, and expectations of the future.

The gains of symbolic representation continue to be extended and refined after 18 months. By about two years of age children begin to compare themselves to various evaluative standards, such as “I am small” or “I am pretty.” Children move into Piaget’s preoperational stage in the third year of life. By this time, they have advanced sufficiently that we may consider the ways in which their thinking differs from that of adults. Piaget’s work reminds us, for instance, that children’s judgments are limited by their perceptions of objects and events and that they have difficulty attending to more than one perceptual attribute at a time (Piaget 1952). Furthermore, egocentrism describes children’s difficulty viewing events in another perspective than their own. Similarly, toddlers at this age may have some difficulty differentiating between subjective experiences and objective reality. Piaget also noted that toddlers use transductive reasoning in which events are believed to be causally related merely by temporal or spatial juxtaposition.

The development of a toddler’s ability to recall experiences of the day and the way the self should look require a memory with more elaborate processes than implicit memory. Paralleling the maturation of the medial temporal lobe and the orbitofrontal cortex, this ability allows the child to have the internal sensation that “I am remembering something about ‘me’.” This ability also requires the increased ability to sequence (possibly a hippocampal function). This non-implicit or explicit memory can be divided into memory for facts (semantic memory), also known as noetic knowledge, and facts about the self (episodic memory), also known as autonoetic knowledge. There is preliminary neuroimaging evidence that these types of memory are functionally quite distinct (Wheeler et al. 1997).

**Emotional Development**

Emotional development at 18 months has been less carefully studied than cognitive or language development. The observational studies of Mahler suggest that exuberance and ebullience of the previous 6 months change as infants become more irritable, more somber, and more clingy. Mahler et al. (1975) view this as evidence of the rapprochement crisis in which toddlers are seen for the first time aware of their own relative powerlessness and ineffectiveness. Stern (1985) has noted that the somberness and irritability of this period derive from the toddlers’ sense of verbal estrangement from their own experience (Stern 1985). That is, their well-developed sense of their own subjective experiences as lived cannot yet be adequately represented by language, leading to observable frustration and emotional turmoil. Nevertheless, it should be pointed out that there have not been systematic investigations validating the observations on which Mahler’s and Stern’s explanations are based, although this remains an important area for future research.

Some of the most important work on emotional development at this transition is that of Lewis et al. (1989) on the emergence of self-conscious emotions, including the emotions of embarrassment, empathy, and envy. They appear not to emerge until the toddler demonstrates self-recognition at about 18 months. Lewis (1994) also asserts that the cognitive development of comparing one’s behavior to an evaluative standard, which probably appears at around 24 months of age, is required for the development of self-conscious evaluative emotions such as guilt, pride, and shame.

Attachment relationships between young children and their caregivers are transformed following the 18- to 20-month transition. The appearance of expressive language, and the enhanced capacity of young children to be aware of the other’s perspective, means that young children must learn to negotiate in order to have their needs met. In attachment terms, the secure base function of parents allows the child to interact more independently with peers and other adults. The safe haven function provides support for the child following separations. In the third year of life, young children are gradually able to sustain relationships in absence of frequent contacts but they still need emotional availability and reasonably frequent contact (especially verbal). Extended separations from primary attachment figures remain risky for the young child’s well being.

**Moral Development**

Emde et al. (Emde and Buchsbaum 1990, Emde et al. 1988) have considered the implications of cognitive and emotional advances at the 18- to 20-month transition for the development of morality. Toddlers at this age are able to generate and monitor their attainment of their goals much more competently than before. They are also able to construct value labels and normative standards based on the evaluation of others (Kagan 1981) and to react with distress to violations of these standards, including broken toys and disapproved-of behaviors (Lyons-Ruth and Zeana 1993).
The emergence of the “moral emotions” of embarrassment, empathy, pride, envy, shame, and guilt at this age are core accompaniments of these various cognitive manifestations of moral development. These emotions have important implications for the infant’s subjective experience of morality (Figure 8–5).

By about 24 months of age, infants begin to demonstrate an internalization of parental standards in the presence of parents, although consistent demonstrations of this in their parents’ absence probably do not occur until at least 36 months of age (Emde et al. 1988). Of course, different parental styles are associated with important individual differences in moral development. Considerable evidence in the US families suggests that power-assertive strategies by parents are associated with an increase in children’s defiant behavior, whereas reasoning and negotiating on the part of the parent facilitate internalization of the parent’s standards (Lyons-Ruth and Zeanah 1993). Committed compliance, a child’s eager embrace of the parental agenda rather than situational compliance, a demonstration of compliance that lacks sincere commitment to parental agenda, has been demonstrated in children as evidence of internalization of parental standards; as committed compliance was observed in situations where the child was alone, whereas situational compliance was not (Kochanska et al. 2001).

Communicative Development
Language makes possible a dramatic advance in the infant’s capacity for relatedness with others. Considerable variability in language production is so common that it is difficult to describe modal patterns. At 18 months, the US toddlers have a median expressive vocabulary of 50 words with a range of less than 10 for those at the 10th percentile to more than 200 words for those at the 90th percentile. Toddlers use word-initial or partial information to understand fluent speech, and the more words they know predicts their accuracy and speed in identifying these words, demonstrating incremental speed processing even before entering the vocabulary spurt (Fernald et al. 2001). Short-term stability in expressive language is high, but the long-term implications of differences at this age are largely unknown (Fenson et al. 1994).

Toddlers use words for a variety of different social functions between 18 and 24 months. Although language comprehension generally precedes production, Bretherton and Bates (1979) found that the magnitude of the gap varied considerably from child to child. New evidence suggests that some infants produce word utterances before they understand the meaning of the utterances, so that comprehension of a particular word does not always precede production of that word.

By age 24 months, the US toddler has a median expressive vocabulary of about 200 words with a range of less than 50 for those at the 10th percentile to more than 500 words for those at the 90th percentile (Fenson et al. 1994). They begin to combine two or more words and to recognize that the combination means more than either word can convey in isolation. Nevertheless, toddlers’ comprehension remains heavily dependent on social cues, as most parents who attempt to have their 2-year-olds “talk to grandma” on the telephone can attest. As toddlers’ language learning progresses, they begin to realize that different forms of messages have different effects on different listeners. Two and 3-year-olds are beginning to infer what listeners know and do not know because they ask significantly more questions when interacting with adults instead of peers, simplify their speech when talking to younger children, and whine almost exclusively in the presence of their parents.

To summarize, all infants progress from cooing to canonical babbling to words to two-word utterances and eventually to meaningful speech. The progression of this development is conserved; however, the timing of each stage is dependent on biological and especially on environmental influences, especially the amount of direct and engaging speech the child is exposed to. As the child begins to develop more proficiency in the realm of his environmental language, his ability to perceive, discriminate, and reproduce nonnative speech begins to decline. Stern (1985) has pointed out that a toddler is on the way to being able to narrate his or her own life stories. This carries with it numerous possibilities for changing one’s view of oneself. What toddlers tell in stories about themselves and how they tell these stories probably have crucial developmental implications.

Social Development
Symbolic representation permits the child to appreciate social relationships more. Most theories of development have emphasized conflicts between toddlers and their...
caregivers because of an increasing move by infants toward autonomy. Interestingly, however, as famous as the “terrible twos” are, there have been no investigations that have addressed the question of difficult behavior in 2-year-olds and whether or not it differs systematically from difficult behavior in 1- or 3-year-olds. A number of contextual factors are probably important, and it is plausible that different infants and toddlers are perceived as more or less challenging at different ages by different parents. As one example, Crockenberg (1987) found that adolescent mothers who had both experienced rejection in childhood and received little support from partners after the birth of their infants were more likely to be angry and punitive with their toddlers; toddlers, in turn, were angry and noncompliant and distanced themselves from their mothers.

In the third year of life, toddlers become far more aware of their relation to others in group and are more sensitive to being included or excluded. Along with increasing independence, toddlers develop a sense of personal space and possession (Emde 1984). At this age, toddlers are able to perceive their own self-efficacy (Bandura 1981). Social relationships, especially attachment relationships, become increasingly important referents for children’s self-appraisal. Sroufe and Matas (Matas et al. 1978) showed that 2-year-old children with secure attachments to their primary caregivers showed more competent autonomous functioning in stressful problem-solving situations. In preschool years, securely attached infants were more socially competent and more ego-resilient than anxiously attached infants (Arend et al. 1979, Waters et al. 1979).

With peers, children begin to move from having little to do with others to engaging in complex and mutually cooperative play. In naturalistic observations of interactive play, parallel play (in which children played in proximity but without interaction) emerged at around 18 months but did not become common until the end of the second year. Episodes of fleeting contact, which contained a clear invitation to interaction but were not sustained beyond one- or two-step exchanges, also emerged as early as 18 months but were more common in the third year (Whiteside et al. 1976).

Dominance hierarchies appear in the third year, presumably as means of controlling aggression. Aggressive interchanges in children’s groups occur almost exclusively among members who are quite close to one another in the hierarchy. This implies, of course, that children are able to detect and respond to subtle social cues about relationships. Troy and Sroufe (1987) demonstrated the behavioral manifestation of such detection by studying patterns of victim–victimizer in pairs of preschool children. They found, as predicted, that children with a history of secure attachment in infancy were neither victims nor victimizers, whereas children with a history of avoidant attachment were always engaged in victim–victimizer interactions when paired with another insecurely attached child.

**Summary of the 18- to 20-Month Transition**

Infants change profoundly during the 18- to 20-month transition. New biological developments appear to make possible significant advances in symbolic representation, which are in turn associated with dramatic cognitive, emotional, communicative, and social advances. Infants are substantially more verbal, both in understanding others’ directives to them and in making their own intentions apparent to others, and this affects both their emotional experience and their social relatedness. Stern (1985) has suggested that the changes at 18 to 20 months also introduce a new sense of self, the verbal self, in which individuals experience both the power and the limitations of language for expressing their most important ideas and feelings.

After all of these dramatic changes, infants consolidate and enhance their new capacities during the third year of life as they prepare to move into wider social spheres of peer and teacher influences in the preschool years. By the time children reach their third birthday they have a sophisticated repertoire of skills for communicating and experiencing relationships. Qualitative features of their caregiving context during the first 3 years of life shape their expectations of relationships as they move into the broader social world.

**Risk and Protective Factors**

Throughout this review of development, we have set aside the biological and environmental factors that may adversely affect infant development and eventually lead to dysfunction. Given the greater understanding of development that is now available, it is important to address how maladaptive patterns appear and how they influence lines of development. A central focus of the research in developmental psychopathology is on describing the processes of adaptive and maladaptive development and the mechanisms by which risk and protective factors influence developmental processes. The impressive cognitive and social competence of infants and the important biobehavioral shifts during this period of rapid developmental change support the notion that infancy is a critical time to study these mechanisms. Furthermore, the emphasis on longitudinal study of these mechanisms has major implications for prevention of mental disorders, and infancy has long been recognized as an important time for initiating preventive efforts (Mrazek and Haggerty 1994).

Research in developmental psychopathology has been influenced by increasingly sophisticated models of development designed to capture the complex interrelationships between biological, interpersonal, and wider social factors. Given this complexity, it is not surprising that research on how risk and protective factors affect development has rarely supported the notion that the transmission of risk is specific and linear in nature (Seifer et al. 1992). For example, maternal depression is related not just to an increased incidence of childhood depression but also to a host of other less specific outcomes (Beardslee et al. 1983). Furthermore, multiple risk conditions from different domains (e.g., biological, psychological, or social) may occur simultaneously and may, in turn, be exacerbated or ameliorated by the care the infant receives (Seifer et al. 1992, Sroufe and Rutter 1984). This has led to the important observation that the total number of risk conditions affecting an infant may be more predictive of competence in later life than exposure to any single specific risk factor (Sameroff et al. 1987). Again this is similar to genetic contributions toward risk.

Rutter (1987) has suggested that the field must move toward understanding protective processes as well as documenting mechanisms by which risk conditions operate.
Indeed, a risk condition that sets off a negative chain reaction in one infant may immunize another against future developmental deviance merely by allowing the infant to overcome that condition (Rutter 1987). In this case, the presence of other risk conditions or of critical protective factors in the infant or environment is likely to account for the difference in outcome.

**Illustrative Risk Conditions**

Defining what constitutes a risk factor or condition is somewhat arbitrary, and many risk factors have been postulated. Nevertheless, the four illustrative areas that are reviewed in this section and summarized in Table (8–5) have been studied extensively. Most studies document effects on broad outcomes of groups of infants and families exposed to a given risk condition, and the results of these investigations provide only limited information about a particular infant and its family. We move from a discussion of broader social risk conditions toward more biological risk conditions, with the important caveat that risk conditions only rarely occur in isolation.

**Poverty**

Poverty has long been recognized as a powerful risk condition with myriad developmental implications. Its effects are considered to be largely nonspecific and may be mediated through many associated factors (e.g., teenage parenting, poor education) that are more common in families that are economically disadvantaged. In fact, poverty is probably best understood as a risk condition that is an aggregate of many separate risk factors. An approach to considering this topic has centered on breaking down poverty into its component parts, allowing the researcher to attempt to tease apart the critical specific factors that are most related to outcomes of interest.

Poverty is defined in the US by household income; currently, the cutoff is $18,100 per year for a family of four. Approximately two-thirds of poor infants are supported by welfare and the same number live in mother-only families (National Center for Children in Poverty 1990). Of the 700,000 poor children younger than 2 years in the US, 40% live in inner cities and 30% live in rural areas. More than one half of the parents of these children have not completed high school, and approximately one half of all mothers in poverty began parenting in their teenage years.

There are biological risk factors associated with poverty, some of which exert influences before birth and contribute to high neonatal and postneonatal mortality indices in this country. From a lack of prenatal care, poor peripartum nutritional status, high rates of prenatal drug and alcohol exposure, and lack of familial support infants born into poverty often face early hurdles. These problems may be compounded by the higher rates of lead intoxication and iron deficiency in poor infants compared with infants raised in more economically advantaged homes. Each of these variables has been shown via well-designed studies to have similar effects on cognitive function in infants; together, they may have synergistic effects that are severe. Finally, rates of hospitalization are higher and lengths of stay longer for poor infants, suggesting a diminished access to preventive medical care.

These biological factors may be ameliorated or exacerbated by a host of psychological and social factors. As with biological risk, there are group differences in the prevalence and severity of the different component factors given later. Although they may be more common in poor families, none are exclusive to poor families, and the clinician is left having to screen for these problems in each individual case.

The most devastating effects of poverty may be on the family, including factors such as parenting style, responsiveness, and resulting family cohesiveness (Rutter 1985). There has been some research focused on parenting style and its relationship to poverty. On the whole, data collected regarding caregiving environments in families faced with poverty suggest that infants may compete for parental attention against many instrumental factors to which parents must attend. Furthermore, there appears to be an overall pattern of reduced or inconsistent attentiveness to infants in these settings, often because of the parents’ own history of inadequate nurturance (Halpern 1993). Not uncommonly, the consequences of this intergenerational transmission of parenting vulnerability include hostile, intrusive interactions by the time of toddlerhood (Lyons-Ruth et al. 1989). These interactions appear to be associated with the increased incidence of anxious and disorganized attachment in samples with low socioeconomic status (Lyons-Ruth et al. 1989, Zeahna et al. 1995) and may interact with other factors to predict insecure attachment across time in low-income families (Egeland and Farber 1984).

The consequences of insecure and/or disorganized attachment have been addressed in longitudinal research.
These patterns are predictive of subsequent behavioral problems, impulse control problems, low self-esteem, disorders of peer relations, and poor cognitive performance (Troy and Stroufe 1987, Lewis et al. 1984, Easterbrooks and Goldberg 1990, Cassidy 1988, Jacobsen et al. 1994). These associations are suggestive of the seeds of disruptive behavior disorders, and longitudinal studies suggest that socioeconomic status is a powerful predictor of, among other things, conduct disorder in children (Kolvin et al. 1988, Offord et al. 1986). The rates of disorder appear to be linked to high-delinquency neighborhoods where children are exposed to high rates of adult criminal behavior, substance abuse, and child maltreatment (Rutter and Giller 1983). Here, the association of poverty with other risk factors for antisocial behavior may represent the final link in a chain reaction begun by poor perinatal nutrition, insufficient maternal responsiveness, and insecure or disorganized attachment.

In fact, it is the accumulation of biological, psychological, and/or social risk factors that account for the association of poverty with numerous adverse outcomes in childhood. Each of these factors appears to exert nonspecific effects, so that the exact mechanisms by which they are related to outcome are difficult to untangle and often inconsistent in different individuals. The clinician is faced with putting the individual puzzle together for each infant to reduce the toll of these complex effects on eventual outcome.

**Child Maltreatment**

Child maltreatment is another broad risk condition related in its etiology to complex interactions between separate risk factors and in its outcome to a variety of possible effects on young children. Physical abuse is the leading cause of death in children younger than 1 year in the US. In 2000, more than 1,000,000 children younger than 3 years were abused and/or neglected. These cases amount for more than two-thirds of child victims in the US (National Child Abuse and Neglect Data System 1992). The first year of life has the highest incidence of maltreatment in all the years from birth to age 18 years, and more than two-thirds of child victims of physical abuse are younger than 6 years (Schmitt and Krugman 1992). The so-called shaken infant syndrome is particularly devastating and is associated with high morbidity and mortality. Intracranial hemorrhages (typically in the subdural space) and retinal detachment that result, along with intra-abdominal injuries, account for most cases of death and disability related to physical abuse in this age group (Waller et al. 1989).

Another common presentation of child maltreatment in infancy is the syndrome of failure to thrive. As many as 35% of all cases of failure to thrive are considered to be due to parental neglect, and it is estimated that 5 to 10% of all children who fail to thrive have also been physically abused (Schmitt and Krugman 1992). Because severe malnutrition in the first 6 months of life may have permanent neurologic sequelae, failure to thrive may be associated with significant morbidity in a minority of cases.

Although there appear to be associations between child maltreatment and poverty, unemployment, child disability, parental psychopathology, parental substance abuse, parental history of child maltreatment, and parental antisocial behavior, none of these conditions alone or in combination are either necessary or sufficient to predict abuse. Attempts to reconcile these facts have led to models designed to understand child maltreatment in the family and in the wider social contexts in which it occurs. In these contexts and influenced by any or all of the associated factors previously given, some parents may withdraw from their children, resulting in neglect; others may strike out at their children leading to emotional and physical abuse: still others may use children for their own sexual gratification. Frequently, different forms of maltreatment exist together in a given family, and there is some evidence that simply witnessing abuse of a sibling or violence between parents may be harmful to children (Hinshaw-Fuselier et al. 1999).

Researchers studying the outcomes related to child maltreatment are similarly challenged to integrate numerous coexisting factors. For infants whose capacities to remember and integrate abusive experiences are different from older children, these issues are doubly complex. The limited data gathered prospectively regarding the effects of child maltreatment on the psychological functioning of infants and toddlers suggest problems in multiple domains of functioning. First, infants who have been abused have disturbed patterns of affective responsiveness (Gaensbauer and Mrazek 1981). Second, they tend to exhibit high levels of anger, especially in interactions with peers during toddlerhood, leading to disturbed patterns of social interactive behavior (George and Main 1979, Main and George 1985).

These problems probably reflect the higher levels of insecure and disorganized patterns of attachment in abused and neglected infants (Schneider-Rosen and Cicchetti 1984, Pianta et al. 1989, Carlson et al. 1989). They also demonstrate early disorders in self-representation (Toth et al. 1997). Finally, they may also be the seeds of subsequent psychiatric disorders linked to abuse in infancy and childhood.

Child maltreatment in infancy is a serious problem in the US and results in significant morbidity and mortality. Some of the morbidity may be apparent in early childhood as an abnormal pattern of social relatedness, and there may be significant long-term sequelae including the possibility of major psychiatric disorders in adulthood.

**Maternal Substance Abuse**

Substance abuse has long been recognized as a major public health problem in the US. Statistics indicating that each year between 100,000 and 375,000 women give birth to infants prenatally exposed to illicit drugs (not including alcohol and nicotine) have generated mounting public interest in this problem (US General Accounting Office 1990). In particular, the rising incidence of crack cocaine use among pregnant women has led to increased research in this area, in part because of the concern regarding direct toxic effects on infants and possible long-term developmental effects.

The tendency for pregnant substance abusers to use more than one drug, and the large number of pre- and postnatal risk factors associated with substance abuse have complicated research in this area. There is no evidence that simple models linking prenatal drug exposure directly to any specific developmental outcome are valid. Instead, as with other broad risk conditions, the interplay among individual biological and psychosocial risk factors must be accounted for in determining the ultimate effect of prenatal drug exposure on infant outcome.
Several important issues in the prenatal period are related to abuse of drugs by pregnant women. First, the drug-using lifestyle is often associated with inadequate nutrition, which may itself affect fetal growth. Second, this problem may be exacerbated by the tendency for substance-abusing women not to receive adequate prenatal care. Third, the issue of timing, dose, and duration of drug exposure is almost never controlled for in studies in this area, although these factors may be critical in determining possible structural effects on the developing central nervous system.

Because these issues are difficult to account for even in the most well-designed studies, the relative effects of drug exposure itself remain obscured. Even the effects of alcohol, long known to have direct effects on the developing neurons as evidenced by fetal alcohol syndrome, appear to be modified by factors unrelated to dosage of exposure (Abel and Sokol 1987, Sampson et al. 1989).

There are also numerous postnatal factors associated with what has been called the culture of drug abuse that may independently affect infant outcome. First, drug abuse appears to be more common among women living in poverty, especially in the inner cities. Second, there appears to be high rates of parental psychopathology associated with substance abuse during pregnancy. Third, caregiving environments for infants whose mothers abuse drugs may be marked by disorganization, with infants often being exposed to multiple caregivers. Thus, there may be direct and indirect contributors to the high rates of insecure and disorganized attachment in infants prenatally exposed to drugs (Rodning et al. 1990). Reports in the media of early research on the effects of prenatal exposure to drugs raised public concern that a generation of “crack infants” would be irreparably damaged, despite the fact that studies were often retrospective and did not control for many prenatal and postnatal associated risk factors. Prospective studies are now under way that attempt to account for drug-associated environmental risk factors while also delineating possible specific neurobehavioral effects. Neurobehavioral effects are understood to be physiological effects on the developing nervous system that may have behavioral manifestations, such as difficulty with state regulation in the neonatal period. The infant’s ability to manage these effects is seen to be partly determined by his or her interactions with the environment, which may serve to heighten or lessen these behavior patterns and their physiological triggers. As yet, there is no consistent picture of what these neurobehavioral effects might even be in the neonatal period, nor are there data on how these effects might be transformed over time (Lester and Tronick 1994).

Some early studies that simultaneously track the long-term impact of teratogenic insult due to prenatal alcohol and drug exposure, and the confounding developmental risks associated with being reared by alcohol and/or drug abusing parents do find direct, mediator, and moderator effects (Jacobson and Jacobson 2001). Main effects mean that one can detect the direct pharmacological effects of drug exposure on long-term child development after controlling for potential confounds. These have been demonstrated for alcohol on cognition and behavior related to prenatal exposure. Main effects on global cognitive development have not been found for cocaine exposure. However, direct effects have been demonstrated on narrow-band information processing tests and subtle behavioral assessments of attention and arousal regulation.

Infants prenatally exposed to drugs and to a collection of these associated risk factors are at high risk for adverse developmental outcome. As with many of the broad risk conditions, this outcome is best predicted by analysis of the number and severity of individual risk factors affecting the infant's proximal environment and the infant's neurobehavioral profile.

### Premature Stress and Serious Illness in Infancy

Premature birth and serious medical illness in infancy represent obvious biological risk factors that may significantly influence infant outcome. Given the wide variability in the causes and limitations of severe medical conditions and premature birth, it is probably the interplay of aggregates of risk factors that may eventually lead to negative outcomes. Interestingly, even with great variability in biological risk factors in preterm infants, psychosocial and especially family factors are most predictive of outcome (Sameroff 1997).

Approximately 3% of births in the US show evidence of major malformations and about 1% of children born weigh less than 1,500 g (Kalter and Warkany 1983a, 1983b, Pharoah and Alberman 1990). This means that approximately 135,000 infants per year are at heightened risk for major developmental problems. However, these numbers do not account for many of the children who eventually suffer from developmental disorders; in fact, developmental disorders occur in 3 of every 1,000 children, a majority of which are not diagnosed until after 2 years of age. Most of these developmental disorders have a primarily biological basis (e.g., chromosomal abnormalities, inadequate fetal blood supply, infections), although 10% are idiopathic (Kopp and Kaler 1989).

Understanding the developmental pathways for children born biologically compromised is complicated by the fact that there are a wide range of degrees of compromise even within types of disorders. This makes outcome research difficult because the groups studied may not be comparable. Furthermore, rates of biological compromise are not equally spread across socioeconomic strata or family composition. For instance, the rate of low birth weight (less than 2,500 g) for healthy white women aged 20 to 30 years is 3%, whereas it is as high as 9% for minority teenagers of low socioeconomic status, a higher proportion of whom are single (National Center for Health Statistics 1987). Although these rates are different primarily because of prenatal psychosocial determinants, these factors define the infant’s postnatal environment as well. As for every infant, the particulars of the proximal environment of the medically compromised infant are powerful determinants of long-term functioning. There must also be some consideration regarding experiences, common in this group of infants, that are of relevance for later development. For instance, the number, length, and timing of hospitalizations in infancy and toddlerhood may affect development significantly (Quinton and Rutter 1976).

Research suggests that the etiology of medical compromise in infancy is likely to be less important than the severity of the compromise and the context in which it occurs. A seriously ill infant burdens parents in many ways,
both direct and indirect. The stress of caring for the infant may affect marital and family relationships. It may also awaken feelings of shame and guilt in caretakers, thereby further compromising the formation of a stable early relationship. There are often significant financial and social burdens that compound these effects and may further destabilize the infant’s proximal environment. Finally, the specific manifestations of the infant’s medical status (e.g., increased irritability resulting from neurological injury) may influence caregiver’s responses.

These problems, common in families dealing with an ill infant, may themselves be potentiated or diminished by associated nonspecific factors such as socioeconomic status or social support. Hence, the context in which the stressors occur helps determine how these stressors affect a given infant and its family. Fortunately, intervention with parents of premature and seriously ill infants often helps to avert a negative chain reaction of parental stressors affecting the infant’s caregiving environment and may improve eventual outcome (Minde 1993).

Like other broad risk conditions, prematurity and serious medical illness in infancy have direct biological effects that may be modified by associated psychological and social factors impinging on the infant’s environment.

Conclusion

The field of developmental psychopathology and the study of risk and protective factors have provided a framework for understanding critical determinants of infant and family functioning and outcome. Poverty, child maltreatment, maternal drug abuse, and serious illness in infancy represent important high-risk conditions. Their eventual effects are determined largely by the associated risk conditions with which they cluster. The mechanisms by which these risk factors exert their main, mediating, and moderating effects are not well understood and may be different for different infants. Still, risk assessment has important clinical implications and future research will better identify these mechanisms. Better delineation of risk and protective factors may lead to better understanding of clinical disorders of infancy and beyond.

Chapter 8 • Infant Development: The First 3 Years of Life

Maturation is a useful concept, but in reality there is only development. (Spitz et al. 1970)

Maturation is a useful concept, but in reality there is only development (Spitz et al. 1970). The preschool period is a time of remarkable development. Toddlers who are “into everything” and require constant parental supervision become kindergartners who can play alone or with peers for extended lengths of time. The 2-year-old who struggles to put two words together in order to communicate a simple desire, turns into a 5-year-old who can tell complex, richly embellished stories. Toddlers who have just mastered the ability to recall information become preschoolers who surprise their parents when they remember events that happened 6 to 12 months earlier, events the parents themselves may have forgotten. In this chapter, development from the beginning of the third year of life until the child enters the first grade is systematically reviewed. The preschool period encompasses rapid growth in all developmental domains, including biological, cognitive, linguistic, emotional, and moral development. Each of these areas and sociocultural influences is addressed. A brief introduction to the field is followed by a discussion of a conceptual framework for considering a range of developmental issues in the preschool period. The chapter concludes with a description of risk and protective factors and a developmental perspective on the ontogeny of psychopathology in this age group.

Historic Considerations

The designation of the preschool period as a unique developmental epoch is relatively modern. Many observers of young children consider the preschool period to be a critical time during which children develop the skills that are necessary to move from the safe haven of the home into the broader social world of school. Historically, psychoanalytic thinkers helped to focus our attention on the importance of early childhood for the future life of the child. Currently, thinking about the preschool years has been influenced by the increase in infant and toddler daycare, as an increasing number of women have moved into the out-of-home work force. Our understanding of development, as of all areas in social science, is embedded in a historical context.

Sigmund Freud (1953) emphasized the role of young children’s thoughts and feelings in influencing their subsequent development, focusing on the child’s oedipal fantasies. He left the field with a rich legacy of interest in children’s individuality and the importance of understanding the meaning of events to children. His daughter, Anna Freud (1965), developed the important concept of developmental lines through her observations of children. She examined the unfolding of different domains of development, much as Piaget (1952) did in his fascinating explication of the cognitive growth of preschoolers. Erik Erikson (1959) further directed our study to the prominent developmental themes of each age period, emphasizing the development of autonomy for toddlers and initiative for preschoolers. He also broadened psychoanalytic interest from the intrapsychic to the world of actual social relationships, anticipating an important focus of current empirical research.

Whereas psychodynamic clinicians have derived their hypotheses about child development predominantly from clinical experience with children and adults, modern developmental psychology requires that observations be subjected to the rigor of empirical research. Developmental studies, as in much of psychiatry, continue to struggle with integrating clinical and empirical insights. Researchers, such as Sroufe (1983), have extended studies of parent–infant attachment to the preschool period, demonstrating both continuities and discontinuities in attachment status through time, as well as delineating some of the negative correlates of insecure attachment. Cicchetti (1989) has examined how normative and at-risk populations of children negotiate stage- salient developmental tasks either adaptively or maladaptively, shedding light on both normal development and the origins of some forms of psychopathology. Broader social influences on children’s linguistic (Bruner 1983) and social
developments (Dunn 1988) are increasingly being studied within cultural context.

**Conceptual Framework**

As children progress from infancy through the preschool years, they attempt to master specific developmental issues and to acquire certain skills. For example, with the advent of walking at the end of the first year of life, children begin to grapple with autonomy issues. However, these issues are not resolved completely within any single developmental period, but they continue to be important throughout the life span (Stern 1985). More or less successful resolution of stage-specific issues leads to healthier or less successful adaptation for the child. Children who do not master stage-specific issues will not inevitably develop psychopathology, but they are at increased risk of subsequent developmental failures and the development of certain psychiatric disorders. This is particularly noticeable when the individual subsequently encounters the same issue in a different developmental form, such as when young physicians once again confront autonomy issues when they complete their long years of training and move into practice. It is often overlooked that this process is frequently positive, offering new opportunities for growth. Each new developmental stage enables the individual to rework past traumas, resolve problematical issues, and master new skills. This positive perspective emphasizes children's potential resilience to trauma and loss, an important area for future research.

Developments within different functional domains do not necessarily progress in concert. A child may be more advanced cognitively than socially. Lines of development are not parallel lines. They interact, supporting or inhibiting growth in other domains, such as when a 3-year-old who has not yet developed much language has difficulty in communicating needs and regulating frustration. Examples of developmental milestones in the preschool period for different developmental domains appear in Table 9–1.

Much of early development occurs within the context of the parent–child relationship. Parents tune in to the skills their young child has and the skills the child needs to acquire in order to move forward to the next phase of growth. Parents who structure their child's learning so that they provide most of what the child needs are helping the child acquire the next level of skill. Vygotsky (1978, 1986) referred to this as working in the “zone of proximal development.” An example would be a parent helping a youngster with a puzzle by orienting the piece so that the child can see where it fits in the puzzle. Another example would be a parent watching a child struggle with the temptation to reach for a forbidden cookie and reminding the child not to take it. By reminding the child of the restriction, the parent helps the child to resist the temptation. Scaffolding the child's development, as this is called, requires that parents provide assistance when needed but do not provide unneeded help.

Modern models of development emphasize that not only do parents influence their children but also children influence their parents. Children within the same family are born with different temperaments, and parents often remark on how different their children are. Over time, children and parents influence each other, mutually affecting the child's developmental trajectory. This is referred to as a transactional model of development. As children grow older, the influences of teachers, peers, and other adults become more important. More recently, we are beginning to understand how genetic influences contribute to these processes. Genes become activated at different times in development. Further understanding of these processes may well result in a major reorganization of our thinking about development in this age group.

These transactional processes result in both continuities and discontinuities in development. For example, there is substantial continuity in aggressive behavior from the preschool to the school-age period. But a happy infant can become a detached autistic 3-year-old, reflecting a major discontinuity in development. Given this overall model of development in the preschool period, the development of different domains will be examined.

**Lines of Development**

**Biological Development**

The field of behavioral genetics is changing the way we think about child development. Behavioral genetics research not only has demonstrated that there are genetic influences on children's development but also has provided the best evidence that environmental influences affect children. By conducting studies of monozygotic and dizygotic twins or of adopted children, researchers can begin to tease apart the genetic and environmental influences on children's cognitive, emotional, and social development.

This research has led to a number of surprising findings that are relevant for our understanding of the preschool period. First, parents have different effects on different children. This is referred to as the effects of the “nonshared environment” (Plomin and Daniels 1987). In understanding children's development, we must focus on how each parent influences each child separately. It becomes more important to examine not the nurturing parent but how this nurturing parent shapes the development of each child individually. Second, genetic influences vary with age. For example, although environmental influences explain significant variability in IQ in childhood, this is no longer true in adolescence (Loehlin et al. 1989). Third, nongenetic factors appear to interact with genetic factors in the development of most psychiatric disorders (Plomin 1994). An exception is autism. Concordance for developing autism is 65 for monozygotic but only 10 for dizygotic twins, indicating a powerful genetic influence for an illness that was initially thought to result entirely from environmental factors (Rutter et al. 1993). Understanding the factors that lead to the expression of genes that carry risk for psychopathology, particularly if the expression of the genes occurs before the first manifestation of the disorder, would contribute substantially to our ability to intervene with infants and young children to prevent psychiatric disorders.

A central principle of neural development is that while brain maturation influences children's behavior, environmental experience also influences neurobiological development. This is evident when we consider brain development. By 18 weeks of gestational age, nearly all cortical neurons have formed and migrated to their neural destination (Sidman and Rakic 1973). However, at birth, the average infant brain is only one-third the weight of the adult brain. There is an important brain growth spurt approximately
at the age of 4 years, and by the age of 5 years, brains of children weigh 90% as much as the brains of adults (Lowery 1986). Much of this increase in size is due to the growth of neurons and their connections. However, increases in brain mass do not tell the most important story.

Another important principle of neurobiological development is that synaptic connections strengthen in response to experience. Activation of both individual neurons and neural networks in response to stimulation increases their likelihood of surviving. This is an important mechanism for the influence of environmental experience on brain development (Changeux and Danchin 1976).

Different brain systems develop at different rates, much as different functional systems develop at different rates. Synaptic density in the frontal cortex peaks at 1 year and pruning of synapses begins by 7 years of life (Huttenlocher 1979). This process occurs earlier in the human visual cortex, where synaptic density peaks at 6 months. Loss of synapses is under way by 1 year of life.

Functional evidence reveals that the brain’s capacity for plasticity varies with age. Young children can recover

*Data are derived from those of Gesell (as revised by Knobloch), Shirley, Provence, Wolf, Bailey, and others. After 5 years, the Stanford-Binet, Wechsler-Bellevue, and other scales offer the most precise estimates of developmental level. In order to have their greatest value, they should be administered only by an experienced and qualified person.

language functions after the dominant hemisphere is damaged (Dennis and Whitaker 1976). However, after the age of 8 years, progress is limited, suggesting that language is represented bilaterally in young children but that it may be represented unilaterally by the early school years (Woods and Teuber 1978). The development of new brain imaging tools is providing a new method for studying the relationship between brain structure and function.

Motor development progresses rapidly during the preschool years (Berger 1994). This is particularly true of the development of gross motor skills involving large body movements such as jumping and running. Whereas toddlers are often awkward in their gross motor movements, most American kindergartners can throw and catch a ball and ride a tricycle. Fine motor skills are more difficult for preschoolers to master. Their limited muscular control, patience, judgment, and short and stubby fingers make it difficult for them to draw or cut food with a knife and fork. Parents who provide a sensitive scaffold for their children, accurately judging their children's abilities and helping them to master the next level of skill, facilitate their children mastering these skills.

The age at which children acquire bowel and bladder control varies among individuals within the normal range. Bowel control is established between 20 and 30 months. Daytime bladder control is acquired in the third year of life, and nighttime control develops between 3.5 and 4 years of age.

Activity level peaks in the third year of life and then decreases (Eaton and Yu 1989). Individual differences in activity level reflect the influences of both nature and nurture. Genetic influences are reflected in the observation that monozygotic twins are more equal in their activity levels than are dizygotic twins (Saudino and Eaton 1994). However, children's activity levels are quite influenced by context (e.g., children are often more fidgety when they are expected to sit quietly, as in school), and cultural expectations influence their level of activity as well. As is true for most developmental domains, genetic, familial, and cultural influences together shape children's activity levels.

A time line of biological development from age 20 months to 5 years is presented in Figure 9–1.

## Biological development

- **20 months – 5 years**

### Bowel control established

#### Daytime bladder control established

#### Activity level peaks

### Nighttime bladder control established

#### Cerebral growth spurt

#### Brain weight 90% of adult brain

**Figure 9–1 Biological development during the preschool years (20 months to 5 years).**

### Cognitive Development

Piaget (1952) believed that the idiosyncratic and, at times, humorous ideas of preschoolers were not random thoughts. Rather, they reflect the activity of inquiring young minds operating according to a unique set of rules. He referred to these rules as the preoperational stage of reasoning. The transition from the sensorimotor to the preoperational stage at 18–24 months is marked by the development of the capacity for symbolic representation. The 2-year-old can store representations of objects in memory, even when not perceiving the objects. This enables the child to recall information. The child in the preoperational stage is capable of symbolic reasoning and symbolic play. A 3-year-old rides a broom as if it were a horse or pretends that a block is a car and races it around the room. These cognitive abilities lead to a fascination with pretend play, which continues until it yields to the school-age child's interest in games, sports, and hobbies.

Parents often take delight in the magical thinking of young children. Piaget’s classification of these idiosyncratic modes of reasoning is valuable as a way of characterizing the children's thought processes. “Animism” refers to endowing inanimate objects with the qualities of living things. For example, young children may say that the sun shines “because it wants to.” “Artificialism” is the belief that all things are made for our use. The child who states that day turns into night because people need to sleep is demonstrating artificialism. “Centration” is the child's tendency to focus on only one aspect of a problem at a time. Young children can identify two rows of five identical objects as being of equal length (Figure 9–2). Yet, if one of the rows is spread out, 3- and 4-year-old children say that the longer row has more objects, centrating on the length of the row (see Figure 9–2). This experiment also indicates that preschoolers are unable to conserve number; the number of items is not conserved across a transformation. Development of this ability heralds the onset of the operational stage of thinking at about 7 years of age.

Although Piaget noticed that young children had difficulty distinguishing surface appearances from underlying realities, careful research has now documented preschoolers’ growing abilities to distinguish reality from appearance. Whereas 3-year-olds have difficulty knowing that a stone...
that is painted to look like an egg is not an egg, older pre-
schoolers readily discriminate the two (Flavell et al. 1983).
This is known as the appearance–reality distinction.

An important extension of this research has been studies
on children's theory of mind. Theory of mind is the term
used to describe the understanding of beliefs, desires, moti-
vations, and emotions as mental states that are ascribed to
one's self and others. This understanding is important for
children, as they seek to make sense of their social environ-
ments, predict how others will behave, and develop richer
and more complex relationships (Wellman 1990). The tra-
ditional experiment for theory of mind development is to
have a child and an adult confederate observe that an object
is hidden in one place. The confederate then exits the room,
and the child observes the experimenter hide the object in
another place. The child is then asked where the confed-
erate thinks it is. Typically, 3-year-olds incorrectly
base their answer on where the object is actually located,
rather than where the confederate thinks it is. Most 4-year-olds do not
make this mistake, understanding that the confederate has
a false belief about where the object is (Wimmer and Perner
1983). This and other evidence about preschoolers' growing
understanding of their own and others' mental states
suggest that at approximately 4 years of life there is a radical
shift in young children's understanding of the mind (Gopnik
1993, Wellman and Bartsch 1988, Wimmer and Weichbold
1994). Interestingly, autistic children do not seem to make
this shift in their thinking. Older children with autism do not
pass the false-belief task, even when their mental capacities
exceed those of normal 4-year-olds (Charman and Baron-
Cohen 1993). By not making the belief–reality distinction,
these children demonstrate that they lack an essential
instrument for interacting with others. Piaget described
preschoolers as egocentric, indicating that they have difficulty
taking the perspective of others. This claim derived from a
famous experiment using a three-dimensional model
of three distinct mountains. Preschoolers are unable to report
which mountain is in front of the other mountains on imag-
ining the model from different angles. Such results do not
demonstrate that young children are egocentric in all ways.
For example, empathy requires the adoption of another's
perspective, and the development of empathy and prosocial
behavior can be demonstrated in young children.

Problems with the Piagetian view of egocentrism reflect
a more general problem with Piagetian stage theory. At the
heart of the theory is the claim that all thinking in one age
period is characterized by certain principles, which can be
elucidated by observing children's performance on specific
tasks. However, the performance of young children is sensi-
tive to even small contextual influences. For examples, when
more familiar materials are used to assess children, they per-
form better.

Attempts to characterize both adults' and children's
cognitive abilities have focused on how information is proc-
cessed. This approach emphasizes children's limited infor-
mation-processing capacities. For example, preschoolers
have limited attention spans. They approach tasks in an
unsystematic fashion, not focusing on the most relevant
features of the task. Their short-term memory capacity is
limited (Case and Khanna 1981). However, when infor-
mation is presented more slowly and the child already has
some background in the area, performance improves, again
demonstrating young children's sensitivity to the contextual
demands of the task.

Although children in the preoperational period can
recall some information, their abilities remain quite limited
at this age. However, their memory is more similar to the
memory of adults than was previously thought. Preschool
children have a good capacity to form generalized event
memories, or scripts, of commonly occurring events. These
knowledge structures are general templates that represent
the expected events in a familiar routine. Children as young
as 3 years old can report what typically happens during fam-
iliar events or routines. These structures are quite important,
as they organize young children's memories. For example,
children use them to make inferences about what happened
when recalling an event. If asked to retell a story that they
have just been told, young children tell it as if certain com-
monly occurring events occurred, even if they never hap-
pened in the story (Nelson and Gruendel 1981). Preschool-
ers may be more able to recall generalized memories than
specific memories of events, known as episodic memories.
Like adults, memories of the past enable children to anticipate future events. Similarly, memory supports preschoolers’ growing ability to outline a plan of behavior to reach those goals, and to sustain the effort to accomplish those goals.

The development of scripts supports the development of transference expectations. Transference expectations reflect the child’s experience or fantasy of how adults act toward them. Children whose parents neglect and ignore their emotional needs may come to believe that adults, in general, will behave in this way toward them. Transference expectations form in response to the normative needs of children to understand their world and to anticipate future events, whether those events are nap time in school or emotionally charged issues such as whether parents act helpfully or punitively toward them (Bretherton 1985, Clyman 1991).

These cognitive abilities also support the development of talents for telling stories and engaging in imaginative play. They permit children to explore what Bruner (1986) has termed “possible worlds.” Children develop imaginary friends, play dress up, and create stories with doll figures. This forms the basis for play therapy. With the support and insight of the play therapist, children can try out more successful solutions to problematic situations or reenact traumatic events, tolerating the disturbing emotions that the events evoke within the safety of the therapeutic relationship. The ability to make narratives of experience helps the child make sense of emotions and relationships. The ability to tell coherent narratives about important issues and events in their lives is an important developmental achievement.

Understanding cognitive development is helpful for both parents and psychiatrists. Although young children are no longer in the sensorimotor stage, in which all reasoning occurs within the context of direct sensory experience, it is often quite helpful to teach them with concrete examples. When explaining a surgical procedure to a young child, a picture is worth more than a thousand words. A sound clinical strategy is to have the child draw a picture of what he or she thinks is wrong. The picture provides a clear view of the child’s understanding of the illness. Preschoolers normatively have a short attention span, substantial distractibility, and an unsystematic approach to tasks. It is, therefore, difficult to establish the level of disturbance required to diagnose attention-deficit/hyperactivity disorder in preschoolers.

A time line of cognitive development from age 20 months to 5 years is presented in Figure 9–3.

**Language Development**

Language acquisition is an enormous accomplishment. Children are exposed to complex utterances and must induce the multiplicity of grammatical rules that permit them to understand and converse in their language. Chomsky (1975) has argued that language development is genetically driven by the formation of specific mental capacities, which he termed the language acquisition device (LAD). His view suggests a strong separation between language and cognition.
and it downplays the role of social processes in language development. Others, such as Bruner (1983), have argued that adults scaffold language input for children. For Bruner, the process of learning language is a shared rather than an individual achievement. Bruner has suggested that language development requires not only a LAD but a LASS as well—a language acquisition support structure—the social environment that supports the child’s growing linguistic abilities.

Linguistic development can be separated into four domains: sounds (phonology), words, methods of combining words (grammar), and sociocultural roles that language serves. Preschoolers are actively acquiring the capacity to pronounce different sounds, which becomes apparent when one compares how 3- and 4-year-olds talk. However, the capacity to form different sounds develops at different rates in this age group.

It is remarkable that children learn the meaning of individual words by listening to how they are used and trying to use them themselves. They tend to learn simpler forms first. A 2-year-old can say “no,” but at 3 years he can say “nobody” and “nothing.” Language learning is an active process, and children make mistakes. Toddlers engage regularly in overextension when they use a word, as if it refers to more than it actually does. They might say “daddy” to refer to all men. Another example of overextension occurred when a 5½-year-old, in describing the relative merits of two toy tanks, said that he or she liked one better because it was “gunnier.” Preschoolers also engage in underextension when they restrict the meaning of a word. An example would be using “animal” to refer only to certain familiar mammals, such as cats and dogs, but not fish. Children by 2–3 years of age learn strong past-tense endings (such as “brought” or “sang”), because these endings are common and useful. They learn these verb forms before they learn to apply “ed” as a suffix to form the past tense for standard verbs, as in “teased.” The development of “ed” endings, which occurs at about the age of 4 years, leads them to switch to overgeneralized versions of verbs that take a strong past-tense ending (they say “bringed” and “singed”). By the end of the preschool period, most young children have sorted out the rules and use these verb forms correctly.

Why do we learn to say “I will let you play” but not “I will allow you play”? Children must learn to use grammar to organize words into sentences so that they can communicate their ideas and wishes. Toddlers begin to understand that “is the door shut?” is often an indirect command and not a question (Shatz 1978). Four-year-olds can take into account who their listener is when speaking. They alter their speech and use motherese when they speak with children who are younger than themselves (Shatz and Gelman 1973). Young children learn an impressive volume of language rules during the preschool years.

**Emotional Development**

Regulation of emotion is a principal developmental task of the preschool years (Maccoby 1980). An emotionally competent 6-year-old can regulate multiple emotions in diverse contexts. An increased capacity for regulation of emotion enables the child to make the transition from the normative dependency and supervision in the home to the broader social world of the school, where greater emotion regulation and self-regulation are expected (Kopp 1989).

Earlier views conceptualized emotions as principally disorganizing behaviors. However, emotions also act as adaptive organizers of behavior. When confronted with a frightening stimulus, a child’s fear organizes a fight-or-flight response. On seeing a novel, loud toy that can elicit either fear or pleasure, infants use adults’ expressions of emotion to guide their behavior. They are more likely to approach the toy if the adult smiles and flee from it if the adult shows fear (Klinnert et al. 1986). This is known as social referencing, and it indicates that emotions can serve functional roles, organizing children’s behavior. Emotion regulation has been characterized as having two component processes. First, children appraise the meaning of the stimulus within the context of their values and goals. Most emotions are elicited through appraisal processes. A leaping tiger induces fear because it can imminently inflict harm. Second, children modulate the behavioral expression of the emotion. Many of the skills that are used to interpret events, elicit emotions, modulate expression, and organize behavior develop in the preschool period.

Central to the social cognitive skills that underlie appraisal processes is a growing ability to think about emotions and relationships. At the end of infancy, toddlers can discriminate emotions by facial expression (Haviland and Lelwica 1987) and differences in vocalizations (Fernald 1992). Their knowledge of the situational elicitors of emotion increases (Denham 1986). They understand that individuals’ desires and beliefs affect the emotions they feel in different situations (Wellman and Woolley 1990). Children understand that people are happy if they expect to obtain a goal, even if they are incorrect in their belief that they will obtain that goal (Harris et al. 1989). They can evaluate the intent of others (Dodge et al. 1986), and they increasingly understand the relationship between emotion and behavior (Denham et al. 1994). These skills support children’s ability to interpret accurately the meaning of events, as emotions are elicited during their day-to-day life.

There are substantial advances in the capacity of preschool children to modulate the expression of emotion. They become better able to modulate their emotional arousal, and preschoolers develop increasingly sophisticated coping strategies to regulate the expression of emotions. They are able to use parents and teachers to organize their emotional responses to disconcerting events. Young children learn to abide by culturally defined rules of emotional expression,
which includes learning to mask emotional expression in certain situations. For example, if 3- to 4-year-olds are promised a gift but are given one they do not want, they inhibit their display of disappointment if the adult who gave them the toy is present but they express their disappointment if they are alone (Cole 1986).

The interrelationship between cognitive and emotional development is apparent in preschoolers’ growing ability to modulate their expression of emotions. Preschoolers develop a capacity to inhibit and delay behavioral plans (Mischel 1983, Gottman 1986), begin to use problem solving in a reflective and planful manner, act in accordance with internalized standards when not in the caregiver’s presence, and develop a sense of personal responsibility for their own actions (Kopp 1989). The role of neural development in these processes, particularly in the frontal lobes, remains an important area of investigation.

One of the most important advances in emotion modulation skills is the ability to use symbolization, language (Cicchetti 1989, Greenberg et al. 1991), and narrative (Buchsbaum and Emde 1990) to express emotions. By the age of 3 years, children can communicate about past, current, and future emotions (Bretherton et al. 1986). However, there are large individual differences in this domain. In a naturalistic, home-based study, 3-year-olds varied from almost never talking about their feelings to talking about them every 2 minutes with their mothers (Dunn et al. 1991). Peers and siblings also play an important role in the development of emotion language. One study found that although preschoolers who were 2 years 9 months old talked more with their mothers about their feelings, by 3 years 11 months they talked more with their older siblings. Interestingly, the children were more likely to comment on their siblings’ feelings than their mothers’ feelings, suggesting that siblings provide an opportunity for learning about others’ emotions that may be less available to only children (Brown and Dunn 1992).

As indicated, preschoolers are able to tell coherent narratives or stories about their experiences. This not only enables them to organize their understanding of the meaning of events but also supports their expressing it in language rather than in action. Play therapy is helpful to children in part because it promotes the development of these skills. This is particularly noticeable when young children learn to put angry feelings into words instead of acting aggressively.

One of the central principles of emotional development is that it occurs within the context of relationships. Children’s primary caregivers are always critical in their emotional development. Interest in how young children develop emotionally within the context of the parent–child relationship has developed primarily from psychoanalytic observations. These investigations have focused on preschoolers’ progressive physical and intrapsychic separation from their parents. Children are increasingly able to tolerate being at both a physical and a psychological distance from their parents for longer lengths of time. Winnicott (1958) described this as the ability to be alone. Mahler and colleagues (1975) characterized this process as the fourth subphase of separation individuation, which they described with the unusual phrase “on the way to libidinal object constancy.” Object refers to the people to whom the individual is relating, in contrast to the index child or subject. Object constancy refers to the ability to calm oneself, self-sooth, and reduce and tolerate anxiety in response to separation from the primary caregiver. Object constancy has been thought to depend on the 2-year-old’s capacity to recall an image of the caregiver as soothing, even when the caregiver is absent. However, object constancy is not an act of memory but is an emotional skill that builds on the child’s growing capacity for recall (Clyman 1991). Difficulties in acquiring object constancy in the presence of disorganizing anxiety has been linked to patients with borderline personality disorder (Kernberg 1975).

Object constancy is believed to be facilitated by achieving a sense of “basic trust” (Erikson 1950) that the infant develops from emotionally sensitive and competent caregiving. Bowlby (1969) characterized this process as the development of a secure attachment to the caregiver. In the preschool period, attachment researchers have focused on the development of internal working models of the attachment relationship, an idea that derives from the work of psychoanalytic object relations theorists (Klein 1948, Fairburn 1954). The hypothesis is that children construct a mental model involving emotions, memories, and sets of expectations of how their caregivers act toward them. Are they warm and nurturing, responding helpfully when the child is hurt, or harsh and punitive? Internal working models may develop from young children’s ability to form scripts of repeatedly occurring events (Bretherton 1985, Clyman 1991, Main et al. 1985). These expectations become a frame, or internal context, within which children appraise the meaning of events. These appraisals then elicit the children’s emotional reactions, organizing their behavior. For example, a child who expects his/her father’s frustration to turn into abusive anger may feel anger or fear and then hide. A number of competing hypotheses address the development of internal working models of relationships (Buchsbaum et al. 1993).

The notion of the Oedipus complex is related to these ideas. In its simplest form, the oedipal hypothesis postulates that young children emotionally and sexually desire the parent of the opposite sex and are angry at the parent of the same sex, with whom they perceive themselves in competition for the opposite-sex parent but also fear retribution from this parent. The Oedipus complex involves developing a set of feelings and ideas about one’s parents and how they feel and are likely to act. Like internal working models of relationships, these ideas and feelings acknowledge the preschooler’s ability to form expectations about others’ actions, which then organize preschoolers’ emotions and behavior. Whereas internal working models are thought to be constructed from actual experiences, oedipal thoughts were believed to develop from the child’s internal fantasies. Furthermore, the theory of the Oedipus complex involves hypotheses about the specific content of those fantasies, such as fear of the parent of the opposite sex. Mental structures become critical in the lives of preschoolers, as they are intimately involved in personality formation.

A time line of emotional development from the age of 20 months to 5 years is presented in Figure 9-4.

**Sociocultural Influences**

Much of children’s socialization occurs within the context of the parent–child relationship. Vygotsky (1978, 1986) described how parents scaffold their children’s development in the zone of proximal development. Parents influence their children’s development predominantly through
their moment-to-moment, day-to-day interactions with their children. They express delight in their toddlers’ growing motoric abilities, supporting the development of pride and self-esteem. They offer them choices when appropriate, supporting their toddlers’ sense of themselves as agents who can have a positive impact on their environment. They teach them social mores as well as moral rules, promoting prosocial behavior and attenuating aggressive behavior. They talk with the toddlers, recalling events of the day, and read stories, encouraging the development of language. They support their enjoyment of imaginative, pretend play, which enhances symbolic thinking and social understanding. They take pleasure in their children’s developing ability to play with peers, supporting a healthy separation from the parents, and their developing autonomy. Above all, children learn about healthy, reciprocal relationships by loving and being loved by their parents.

Baumrind (1971) has delineated four general styles of parenting (Table 9–2). The authoritarian style parent is demanding, is controlling, and makes frequent use of threats and punishment. This parenting style correlates with having children who are moody, irritable, aggressive, and at higher risk of developing disruptive behavior disorders. Indifferent parents set few limits, engage in less monitoring of their children’s behavior, and often appear detached. Their children tend to be demanding, tend to be less compliant, and have poorer interpersonal skills with peers. The permissive style parent is loving, is emotionally available, tends to set few limits, and is accepting and encouraging. The children are often impulsive and have behavioral problems. The authoritative parenting style is characterized as caring, emotionally available, setting appropriate limits, and maintaining structure and reasonable expectations for the children. The children in turn are more independent, have better social skills, and are more self-confident.

Siblings and peers become increasingly important to young children during the preschool years. Preschoolers tend to spend more time with peers and less time with adults than toddlers. In turn, siblings and their peers influence the development of social and cognitive skills in their younger brothers and sisters (Lamb 1988). Children who compete with siblings for toys or for their parents’ attention may be more motivated to decipher what others think and feel, which may support the development of social cognitive skills (Berger 1994). These skills can then be used either to please or to annoy their siblings (Dunn 1988). An interesting finding in this area is that, although young children are more likely to be rivalrous with their siblings than with unrelated peers, they are also more likely to be more cooperative and nurturing with their siblings than with other children (Berger 1994).

There are sex differences in the development of children’s peer relationships that are evident by the age of 2 years. Boys are more aggressive, more likely to engage in...
rough-and-tumble play, and more apt to play with objects that can be manipulated, such as blocks or trucks. Girls often prefer doll play, dress up, and artwork. However, children of both sexes engage in both types of play. Children in all cultures prefer to play with same-sex partners, which is known as gender segregation. These preferences are evident by 33 months and increase during the school years. There is a long history of debate over whether sex differences primarily reflect the influence of nature or nurture. Observations of parents clearly document differences in their behavior toward children of different sexes. However, the degree to which these differential parental behaviors occur in response to genetic variation rather than in response to cultural demands to shape early behavior remains unclear.

Much of children's cognitive and social learning occurs through play. Preschoolers progress through four stages of play: solitary play, in which children play alone; parallel play, in which children play side by side but limit their interactions; associative play, in which children share toys but do not adopt roles or cooperate to reach a goal; and cooperative play, in which the latter features become prominent (Parten 1932). Solitary and parallel plays decrease and associative and cooperative plays increase during the preschool years. However, children continue to engage in all forms of play. In the preschool years, children increasingly enjoy pretend play, which allows them to try out new roles and experiences and master difficult feelings. By the beginning of elementary school, children become more interested in rule-governed games, which support the growth of collaborative problem solving.

Daycare has become an important caregiving environment for young children. This has raised questions about its influence on children's development. Some studies suggest that children may be less likely to develop secure attachments to their parents if they have more experience in daycare. However, children may also develop secure attachments to their daycare providers. Intellectual and linguistic development may actually improve for middle-class children cared for in good daycare centers (Clarke-Stewart 1984). These children tend to be more self-sufficient and less dependent on their parents. Findings are mixed on other variables: children may be more knowledgeable about and more comfortable in social situations, yet they may be less compliant and more aggressive than children not exposed to daycare (Cole and Cole 1989). These studies suggest that the quality of the daycare is the critical variable. Larger daycare centers are less likely to let children initiate activities, and they tend to emphasize rules to maintain order. Teachers may be less likely to be sensitive to the individual needs of children (LeVine 1980).

There has been increasing recognition of the importance of cultural influences on children's development. Children develop within a culture, acquiring many of its expectations and patterns outside their awareness. The meaning of their behavior can then be understood only within the context of those cultural patterns and norms. For example, when children are evaluated for depression, we must understand whether the child's culture values concealing or expressing emotion. Children who learn not to express emotion may be seen as having a flat facial affect, which can be misinterpreted as reflecting depression. It is essential to understand the functional meaning of a behavior as it is understood within the child's culture.

These issues have become more prominent as we have increasingly appreciated the cultural and class bias in previous developmental studies. Most studies of child development, including those reviewed in this chapter, have focused predominantly on middle-class, white families. This has made it difficult to know what is universal and what is culture specific in children's development. This is critical because research indicates that cultural variability is prevalent in children's development. Another example is the cross-cultural differences in siblings' roles. Many non-Western, nonindustrialized cultures encourage children to be important caregivers for their younger siblings (Weisner 1982). Parents' use of praise (Whiting and Whiting 1975) and children's attention-seeking behavior (LeVine 1977, 1980) show marked cross-cultural variation. Many cultures do not value independence and assertiveness in children to the extent that they are valued in the majority American culture, instead emphasizing caretaking and mutual responsibility (Whiting and Child 1953). These differences may have an important impact on children's social development.

A time line of social development from age 20 months to 5 years is presented in Figure 9–5.

**Moral Development**

Why do children learn to behave in accordance with societal standards? It is not simply a matter of learning social mores and moral rules. Some children know what is expected of them but are not motivated to comply. Other children want to follow their parents' directives, but they find themselves becoming angry and aggressive and then regretting their destructive actions. These observations illustrate the complexity of the cognitive, emotional, and motivational demands on children.
processes involved in moral behavior. Central to these processes is the principle that moral development, like emotional development in general, occurs within the context of relationships. Parents influence the moral development of their children through their moment-to-moment interactions with them. They communicate their expectations both explicitly and implicitly. They model acceptable behavior, both self-consciously and without forethought. They help their children to regulate their anger and aggression and to act prosocially, learning to share their toys and to act fairly with their friends. Children internalize their parents’ expectations within the context of a loving relationship with them.

The value of a broad perspective in understanding moral development has been articulated. This view emphasizes the central role that emotions play in organizing moral behavior, the early development of moral motives and behavior in the infant and toddler years, the importance of shared experience with others in internalizing moral emotions and values, and the role of nonconscious information processing in moral behavior (Emde et al. 1991). This view stands in contrast to the historically important views of Piaget (1952) and Kohlberg (1982), who argued that moral development begins with the acquisition of perspective taking, with the onset of concrete operations at about the age of 7 years.

The development of moral emotions is a critical process for children’s moral development. In the first years of life, infants express the basic or Darwinian emotions, which include anger, happiness, sadness, fear, surprise, and disgust. These emotions appear to be neurobiologically hardwired, are tied to characteristic facial expressions of emotion, and appear across cultures (Ekman 1971). Beginning in the second year of life and continuing through the preschool years, the moral emotions of empathy, pride, shame, and guilt develop. Unlike the basic emotions, they do not all have characteristic facial expressions, are more internal yet appear to develop from shared experience, and arise either in situations of conflict or in response to internalized standards. Like all emotions, they play functional roles in motivating and organizing children’s behavior. Only when they are particularly intense are they likely to disorganize or dysregulate children’s behavior.

Toddlers show anxiety when internalized standards are violated, such as when they are presented with a flawed toy or doll (Kagan 1981). This emotion signals a violation of a norm. Empathy also develops quite early. Infants in the first year of life cry in response to another’s distress. By the end of the second year of life, toddlers comfort others who are hurt or crying, patting them gently or bringing them a favorite blanket (Zahn-Waxler et al. 1979). This finding was critical in focusing research attention on early moral development (Radke-Yarrow et al. 1983). Empathy, like pride, is important in the acquisition of the “do’s” of moral development (Emde et al. 1988). Although parents (and researchers) tend to focus on the “don’ts,” that is, children’s misbehavior, children often act in accordance with parental and societal standards without a sense of struggle or conflict. Early games involving turn taking and reciprocity, such as an infant and an adult handing a shiny toy back and forth, may set the stage for sharing and early prosocial behavior. Empathy can motivate children’s prosocial behavior in the absence of conflict. A twin study has demonstrated that both empathic concern and prosocial behavior are under some genetic control, although to different degrees at different ages (Zahn-Waxler et al. 1992). This should not surprise us, because altruistic behavior may increase the likelihood that a social group reproduces, therefore increasing the probability that altruism is selected for in evolution (Wilson 1975). This view stresses the role empathy plays as a critical mediator of early moral development.

Pride also develops early in childhood. Like embarrassment, shame, and guilt, it evokes a relationship with a significant other who has set a standard that the child has internalized. Pride involves pleasure over meeting that standard and may be expressed with one’s head held high, a puffed-up posture, and a puffed-up feeling. Young children are excited and proud when they experience themselves as agents who can have an important effect on people and events in their world (Erikson 1950). In contrast, shame and embarrassment evoke an image of the significant other casting a disapproving look, and the child wishes that he or she could escape from being seen. Shame and embarrassment are remarkably visual emotions. Guilt is an auditory emotion in that we readily evoke the significant other’s disapproving voice. Guilt appears later than the other moral emotions, although it may develop from earlier reparative behaviors (Zahn-Waxler and Kochanska 1990). Whereas guilt appears to be invoked when a child feels that an act was bad, shame appears to arise when it is the self that is evaluated negatively (Lewis 1992).

Moral emotions evoke a sense of shared experience with important others that are central to the process of moral internalization. By the end of the first year of life, children engage in social referencing, looking to an adult when they are uncertain and modifying their behavior depending on the adult’s emotional response. This interpersonal emotional signaling is transformed into internal emotional signaling with the development of moral emotions. Moral emotions alert us to possible or actual rule violations, invoking an auditory or visual representation of the significant other’s emotional response.

The acquisition of moral and social rules also develops from shared experience. Young toddlers who are repeatedly told not to approach a stove become older toddlers who utter “no” or “hot” to themselves when they walk near it. However, rule internalization is quite tentative at this age, and toddlers typically regulate their behavior “under the watchful eyes of the caregiver” (Emde et al. 1988). It is not until later that they learn to withstand temptation by themselves without direct adult support. But there is developmental continuity in these processes from quite an early age.

The acquisition of regulatory rules often occurs outside conscious awareness (Clyman 1991). Just as children learn to use grammatical rules before they learn in school how to articulate those rules, young children learn to behave in accordance with parental and cultural standards before they can articulate, or are even conscious of, those standards. Indeed, a child can acquire moral and social rules even if adults never verbalize them to the child. Much of psychological research is directed at articulating the rules that govern human behavior, even though individuals are not conscious of those rules. This is particularly true for moral and social standards.

As the child moves directly into the preschool period, social cognitive processes become increasingly important
in mediating development in the moral sphere. Young children are increasingly able to appraise the meaning of others’ behavior and to interpret social cues. They develop an understanding that others have feelings and intentions. This is referred to as acquiring a theory of mind, realizing that others have thoughts, feelings, and desires as we do. Children also begin to deceive others in the preschool years, perhaps because they understand that others can hold beliefs that are not true. Ironically, this is a developmental achievement (Hay 1994).

Preschoolers begin to justify their prosocial actions. In response to teacher’s directives, they explain that one should obey authority figures or indicate that they fear punishment. However, when justifying prosocial behavior toward friends or peers, they refer to their relationships with them or comment on their needs (Eisenberg et al. 1985). By the end of the third year of life, children can distinguish between social conventions (e.g., not to place your elbows on the table) and moral rules (e.g., not to hurt others), and they know that moral violations are considered more serious (Smetana and Braeges 1990).

Children also develop more sophisticated strategies for coping with temptation. Mischel (1983) and Flavell (1985) offered preschool children a choice of an immediate reward or a more desirable prize after some delay. Few young preschoolers spontaneously develop delay strategies. However, when the researchers provided the children with strategies, such as trying to distract themselves, they were able to use them to resist the temptation. Similarly, parents teach their children to regulate temptation within the zone of proximal development.

The development of preschoolers’ capacity for narrative permits them to talk about moral events and to consider alternative outcomes. Moral themes are frequent in young children’s doll play. Children as young as 3 years old can struggle with simple moral dilemmas, if presented to them in an age-appropriate form (Buchsbaum and Emde 1990). They struggle, for example, with whether they should help an injured peer even if it means disobeying a parental directive. There may be substantial variations in how children resolve moral dilemmas, depending on their caregiving environment (Buchsbaum et al. 1993).

Psychoanalysts have focused on the oedipal narrative as central to moral development. In this view, the resolution of this conflict leads the child to internalize the same-sex parent’s standards and ideals, resulting in the formation of the superego. The Oedipus complex builds on preschool children’s ability to narrate experience, think about other’s feelings, experience guilt, and entertain alternative possible worlds. Whether the Oedipus complex is central to moral development and personality formation continues to be debated both within and outside psychoanalytic circles (Kohut 1977). We know, however, that the traditional psychoanalytic view did not adequately address females’ experiences or moral development before the age of 4 years and that it overemphasized the role of fear of retribution and guilt without adequately appreciating the part played by empathy and reciprocity in young children’s moral development.

A time line of moral development from age 20 months to 5 years is presented in Figure 9–6.

### Risk and Protective Factors
Modern theories of developmental psychopathology suggest that psychiatric disorders develop from the interaction of risk and protective factors in development. Children with more risk factors and fewer protective factors are more likely to develop psychiatric disorders. Risk and protective factors operate at multiple levels of influence. There can be child factors such as prematurity or attentional problems, genetic factors such as functional polymorphisms, nongenetic biological factors such as closed head injuries, parental influences such as maltreatment, family influences such as the protective value of growing up with caring grandparents or other concerned adults, community influences such as the availability of treatment services, and societal influences such as the current prevalence and toleration of violence in America.

These risk and protective factors can influence all domains of children’s development. For example, children who are maltreated are more likely to have language delays and to be angry and aggressive. These risks interact with the

---

**Figure 9–6** Moral development during the preschool years (20 months to 5 years).
availability of community services, such as early intervention programs. Preschoolers may be particularly sensitive to the influence of risk and protective factors because development is so rapid in this period. Their influence is best understood within the broader context of developmental psychopathology.

**Developmental Psychopathology**

Developmental psychopathology posits that the ontogeny of psychiatric disorders can best be examined within the context of normal development (Cicchetti 1989, Sroufe and Rutter 1984). For example, the meaning of temper tantrums can be understood only if we know the age of the child. Temper tantrums in a 2-year-old have a different meaning than a tantrum in a 10-year-old. Atypical development provides an “experience in nature” (Bronfenbrenner 1979) that illuminates our understanding of normal development. Just as the normal functioning of the islets of Langerhans was determined by studying diabetic patients, we can learn about normal development by studying psychopathological variations.

Multivariate, transactional models are used to understand the reciprocal influence that the child and the caregiving environment have on each other over time. The balance of risk and protective factors is critical in influencing the child’s outcome. Risk is considered probabilistically. Inability to master developmental tasks at one age places the child at increased risk of subsequent developmental difficulties. But later developmental challenges offer new opportunities for emotional growth. Outcomes are often evaluated as healthier or less optimal adaptations to exigent conditions, both environmental and genetic. Psychopathology is often evaluated dimensionally, examining, for example, more or less aggression, emphasizing the continuities between normal and atypical development. This view stands in contrast to the biomedical, categorical perspective that characterizes psychiatric diagnoses. The perspective of developmental psychopathology can be illustrated with an example.

The disruptive behavior disorders, including attention-deficit/hyperactivity disorder, oppositional defiant disorder, and conduct disorder, are the most common reasons for presentation to child psychiatric clinics (Robins 1991). Disruptive behavior is particularly common in the preschool period. However, judging whether oppositional and aggressive behavior reflects a psychiatric disorder is often difficult in preschoolers, because some defiant and aggressive behavior is normative in this age group, as children struggle to define themselves, separate from parents, and modulate their strong emotions.

There is growing evidence of continuity in disruptive behavior patterns from preschool to later childhood. Examining 3-year-olds with disruptive behavior problems, Richman and colleague (1982) found that the problems persisted, both at home and in school, at the age of 5 years. However, stability of behavior problems was associated with a range of risk factors operating at multiple levels of influence, including family factors (marital conflict, maternal depression, and punitive child-rearing styles) and social factors (including poor housing and financial difficulties). Child factors are important as well. Children with early language difficulties are subsequently at risk of both emotional and behavioral disorders (Stevenson et al. 1985). Early disruptive behavior is associated with other outcomes, such as internalizing disorders, reading difficulties, and low school achievement (Stevenson et al. 1985, Campbell 1990). Severe behavior problems in preschoolers can also predict multiple difficulties into adolescence (Lerner et al. 1985). Protective factors operate as well. For example, stable family functioning can prevent early temperamental difficulties from developing into later behavioral disorders.

Research has focused explicitly on the development of aggression and has shed light not only on the normative development of aggression but also on the development of pathological aggression and ways to prevent it. Historically, studies of violent individuals began with adolescents and followed them to adulthood. This led researchers to conclude that aggression peaked during late adolescence and young adulthood and decreased afterwards. This view also reflected the dominance at that time of social learning theory (Patterson 1982), which held that the children who would become violent later in life learned to be aggressive in childhood (Trembley 2004).

More recent longitudinal studies, begun with toddlers, have changed our view and reached two major conclusions. The first conclusion is that aggression peaks between 2 and 4 years of age, not late in adolescence or early adulthood (Trembley 2002, Côté et al. 2006). The second conclusion is that children typically fall into three major groups. For example, a nationally representative Canadian study of 10,000 children from 2 to 11 years of age found that about one-third of the children were essentially never aggressive across this age span, one-half were occasionally aggressive as toddlers and preschoolers but their aggression decreased until they were not aggressive by the age of 11 years, and one-sixth were already highly aggressive by the age of 2 years and remained so until they were 11 years old (Côté et al. 2006). These studies have dramatically changed our understanding of the normative development of aggression, have helped shift prevention efforts to focus on infants and toddlers, and have suggested that a major prevention strategy is to help young children regulate their anger and aggression, in contrast to the social learning approach of helping children to not learn to be aggressive from their parents (Patterson 1982).

Developmental psychopathology models continually confront us with the complexity of the development of preschool-age children. Both those who are at risk and those who are developing well provide insights into what young children can do, what they can learn, what they can feel, and what they can understand.

Plomin R and Daniels D (1987) Why are children in the same family so different from each other? The Behavioral and Brain Sciences 10, 1–16.

The age span discussed in this chapter is 6 years to puberty. Demarcating this period as school age is an artifact of the public school system. However, research supports the concept that this period of childhood is a discrete stage in which new skills and neurodevelopmental capacities evolve. Freud (1905) discussed this phase of development as the result of the resolution of the Oedipus complex and noted subsequent reorganizations in behavior. Piaget (1929) emphasized that in this period the child achieves a new stage of operational thinking associated with new capacities for learning. He provided a detailed description of the concrete operations that bridge the preoperational stage and the later advent of abstract operations. This period has been characterized by different labels that reflect their theoretical origins. Freud referred to this period as “latency” to designate that early infantile sexuality is repressed and remains latent until puberty. Erikson (1963) called it the “age of industry,” signifying the tendency of children during this stage to be persistent and task oriented. Sullivan (1940) simply referred to it as the “juvenile era,” offering an explanation of the consolidation of early attachments and the bridge into adolescence.

Each of these models is based on the concept that there is a discontinuity from toddlerhood. Thomas and Chess (1977) argued that this period should simply be called “middle childhood,” with the warning that more specific names represent the strong biases of theories. Some of these perspectives indicate continuities from early childhood into adulthood. Werner (1957) provided an alternative perspective of discontinuity and hierarchical reorganization, indicating that new functions emerge that are not easily derived from prior stages. Shapiro and Perry (1976) argued that the behaviors that become apparent during the period of middle childhood cannot be clearly foretold from the epigenetic sequences of the prior lives of children. Indeed, this is a period marked by a greater capacity and consequent opportunity to learn. These achievements have sufficient consistency across cultures to be considered a maturational discontinuity. These new capacities have been recognized repeatedly by new social roles as well as new cognitive capacities. Drawing on Spitz (1965), Emde and colleagues (1976) developed the concept of biodevelopmental shifts, based on a maturational succession of organizers that evolve in average expectable environments.

Puberty marks the end of this period and is associated with the onset of adolescent behaviors that are shaped by cultural expectations. However, puberty is not equivalent to adolescence, despite the reality that adolescence is often initiated by various social and religious rituals that presuppose biological maturity.

Middle childhood has been divided into early and late stages. In schools, the curriculum of pre-fourth graders focuses on reading and writing before the introduction of integrative studies such as social sciences and literature. Gesell and Ilg (1949) have provided the best behavioral descriptions of normal American school-age children. These studies began in the 1930s but are still valid. They wrote, “There is a kind of quieting down at seven. Six-year-olds tended to produce brash reactions and bursts of activities. The 7-year-old goes into lengthy periods of calmness and self-absorption.” They further remarked, “At home, as at school, the child’s personal social behavior shows an increasing awareness of both self and of others. He is more companionable…He is not a good loser. He tattletales. If a playground situation grows too complex and things go badly, the 7-year-old runs home with a more or less righteous declaration, ‘I am quitting.’ Let us be duly grateful for his germinating righteousness. It is evident that the 7-year-old is developing an ethical sense.” Concerning 8-year-olds, Gesell and Ilg continued, “Eight is more a person by adult standards and in terms of adult–child relationships. One converses with an 8-year-old with lessening condescension. …There are three traits that characterize the dynamics of his behavior: speediness, expansiveness, evaluativeness. The 9-year-old is no longer a mere child, nor is he yet a youth. Nine is an intermediate age in the middle zone which lies between the kindergarten and the junior high school teens.”
Within 4 years, there is a significant behavioral reorganization. There is a growing preoccupation with self, but also an increased interest in peer relationships. An expanded moral and social orientation helps the child first to bridge the preschool period with the new period and later to move into adolescence. Thus, middle childhood can be understood as a bridge as well as a stage in its own right. Moreover, it is a time in the life of a child when he/she is gathering the tools that will lead to a more adaptive adolescence.

**Conceptual Framework**

The concept of lines of development outlined throughout this section provides a means of considering development in a dimensional manner. Anna Freud (1965) defined conceptual developmental lines (Figure 10–1) moving from egocentricity to companionship, from body tyranny to mastery over one’s body, and from dependency to independence. All of these transitions represent examples of the tasks that are partly accomplished during middle childhood. There are times when some functions and skills lag behind others, and yet we can recognize a child who is passing through middle childhood.

Children of 6 and 7 years have long been believed to have achieved the capacity for some degree of independent action. In our culture, children remain dependent well into adolescence, but it is recognized that 6- and 7-year-olds are able to attend school and learn the basic skills that are necessary for his/her education and adaptation. Preschool and kindergarten currently provide early socialization experiences that previously occurred within the family. Preschool gatherings are preparatory for “real” schoolwork. Kohlberg and Gilligan (1971) commented that all cultures recognize “two great stages of transformation and development”: one is at 5–7 years and the other is in adolescence.

The Roman Catholic Church considered the age of 7 years to be the age of reason (Aries and Baldick 1962) and recommended that first communion should appropriately take place then. Similarly, the early English kings determined that the age 7 years was significant for common law. Children younger than age 7 years were believed to be incapable not only of criminal intent but also of taking an oath to testify in a courtroom. At 7 years, boys were apprenticed as tradesmen and artisans to learn specific skills (Pinchbeck and Hewitt 1969).

During the industrial revolution, 7-year-olds were employed as laborers in factories. Because of their size they were often given positions as chimney sweeps or mine crawlers, which placed them at increased risk of a variety of industrial diseases and physical abuse. In the USA, the child labor laws were among the first laws to protect children. Children younger than age 7 years were believed to be incapable not only of criminal intent but also of taking an oath to testify in a courtroom. At 7 years, boys were apprenticed as tradesmen and artisans to learn specific skills (Pinchbeck and Hewitt 1969).

Freud looked at postadoipal latency as a major step in the development of the rules of civilized behavior (Shapiro 1977). Freud was presaged by Diderot and St. Augustine regarding the moral development of children. Diderot (1966) wrote, “If the little savage were left to himself, preserving all his foolishness and adding to all the small sense of a child in the cradle the violent passions of a man of thirty, he would strangle his father and lie with his mother.” Augustine earlier wrote, “If babies are innocent, it is not for lack of will to do harm, but for lack of strength” (Rudnynsky and Spitz 1994).

The Oedipus complex provides a basic human formula containing the permutations of the experiences of the developing child directed toward the first two important objects of dependence—mother and father. Freud’s (1926) hierarchy of anxieties or danger signals includes the threat of castration as a mental deterrent to the wishes of this period and leads to repression of the constellations that are again revived in postadolescent children. Bornstein (1951) suggested that there is “a persistent denial of the struggle against the breakthrough of instinctual impulses” during the early period. Former lively desires are repressed and the latency child directs energy to the accomplishment of age-appropriate tasks.

There is sufficient variation in the course of middle childhood to lead some observers to question the capacity of the theory-driven model to explain the phenomena encountered. Longitudinal studies that traverse latency suggest a more linear developmental course (Thomas and Chess 1972, Offer and Offer 1975, Hauser et al. 1991). With the emergence of industriousness, an increase in number and kinds of relationships, and the importance of belonging to peer groups, five emergent patterns of development have been described. The first is characterized by a steady developmental progression through this period (Offer and Offer 1975, Neubauer and Flapan 1976). A second group has behavioral difficulties early in life, which are resolved during middle childhood. A third group presents with early behavior problems and develops new problems in middle childhood that are associated with new stressors. A fourth group has early behavioral problems that persist into middle childhood. A fifth group demonstrates entirely new problems in middle childhood.

A more specific group of children known as *difficult children* was distinguished by Chess and Thomas (1984). Difficult children express early behaviors that are correlated with later school problems, social difficulties, and psychiatric disorders. They show slower adaptability to new situations and intense negative reactions to stimuli.

Persistent difficulties from preschool through latency were first described in a London epidemiological study (Richman et al. 1982). Polysymptomatic 3-year-olds were found to show persistent trouble when they were followed up at 7 and 9 years of age. However, early epidemiological studies demonstrated that, with advancing age, there is a decrease in the prevalence of behavior disorders in middle-school age children (LaPouse and Monk 1959, McFarland et al. 1954). Later longitudinal data drawn from the Dunedin studies show some persistent continuities (Caspi et al. 2003).

**Biological Development**

Early biologically oriented investigations described the gradual cephalocaudal maturation and intersensory integration of the developing child with specific documentation of the discontinuities that seem to occur at ages 6 and 7 years. Many investigators showed the increasing regularity of mature development.
performance on a variety of visual–motor and neuroperceptual tasks by the age 7 years (Piaget 1929, 1948, Pinchbeck and Hewitt 1969, McFarland et al. 1954, Pollock and Goldfarb 1957, Pollock and Gordon 1960). Seven-year-olds appreciate two simultaneous stimuli and can make more complex visual–motor and intersensory integrations. Seven-year-olds can also have established handedness, eyedness, and footedness, and haptic–auditory and auditory–visual integrations are more reliable (Birch and Lefford 1967). Motility is better integrated, motor sequencing behaviors are performed more accurately and smoothly, and athletic prowess emerges. Delays in some of these achievements have been called soft neurological or nonfocal neurological signs. If three or more signs are present in children older than 7 years, associations with psychopathology have been demonstrated (Hertzig 1982).

Magnetic resonance technologies, magnetic resonance imaging (MRI) and functional magnetic resonance imaging (fMRI), are techniques for capturing features of brain development. Understanding the development of pathways underlying cognition, the experiences (experience-dependent learning) that alter them, and the patterns of physical development (maturation) that support them, should guide the study of both typical and atypical school-age development. Studies have shown that cortical maturation corresponds to milestones in cognitive development (e.g., Gogtay et al. 2004, Sowell et al. 2004). Motor and sensory systems supporting primary functions are earliest to mature. Temporal and parietal association cortices involved in basic language skills and spatial attention follow and are the last to mature. Higher-order association areas, such as the prefrontal and lateral temporal cortices, modulate basic attention, and language processes (Gogtay et al. 2004, Sowell et al. 2004). Structural MRI studies show that loss of cortical gray matter occurs earliest in the primary sensorimotor areas and latest in the dorsolateral prefrontal cortex (Gogtay et al. 2004, Reiss et al. 1996). Shaw and colleagues (2006) report a shift in the correlation between IQ and cortical thickness with development. Specifically, the correlation is negative in early childhood but becomes positive in late childhood and beyond. The level of intelligence was found to be associated with the trajectory of cortical development in frontal regions. While grey matter decreases in a U-shaped fashion observed in subcortical regions that project to association networks. Any distracter from the cue can increase reaction times if the distracter cannot be inhibited as nonsalient. In accord with the general rule of greater specificity and greater capacity to eliminate noise in favor of signal, school-age children become progressively better able to accurately respond, and the brain activations concurrently approach adult levels as the children mature (Posner 2001).

The time line in Figure 10–2 presents biological development from age 6 to 12 years.

**Cognitive Development**

Piaget raised the question of what cognitive mechanisms underlie children’s reasoning. His followers were able to achieve a new understanding of invariant sequences in cognitive development. These observations of basic developmental sequencing have been repeatedly demonstrated.

The initial cognitive sensory–motor organization of the child evolves to the preoperational stage after the child attains object permanence. However, it is not until about age 7 years that concrete operations are achieved, permitting children to effectively learn and utilize school instruction. A number of significant transformations become possible with operational intelligence. There is a shift from egocentrism to being able to take another person’s vantage point. An examiner can ask what the room would look like from the perspective of another. There is a shift to conservation of material volume and quantity and a shift to reversible operations. At this point, children can begin to understand that their speech and language are useful for social aims and story telling rather than simply for conveying desires and wishes.

The formal capacity for taking the vantage point of another on a perceptual task suggests a newfound possibility for perspective taking in emotion and empathy as well as achieving a firmer theory of mind. Up to age 7 years, simple repetition or monologues are possible. However, preschool children do not have true topic maintenance. Explanations are often noncausal and are cast in a mere sequential juxtaposition of desires, wishes, or events. Preoperational children use the word “because” nonconsequentially. By contrast, the concrete operational child can produce causal sequences. The child can now make predictions about relationships or about past–future relationships. In anticipation of going on a trip, the child can say, “When we get to Grandma’s home, we’ll go to the room that she has for us, and we’ll put our toys away, and then we can go downstairs and have dinner, and then you can tuck me into the new
This sequence suggests that memories are operative and based on past experiences. Forward-looking adaptive discussion is possible.

The child of this age can understand that transformations of form can take place even though there is a constant material basis in reality. Thus, toys called “transformers” are based on the idea that a basic material module can be changed by manipulation of its parts. Noticing that the actors in a theater are actually children or adults who take on parts and then return to their former roles as ordinary persons is a feature of conservation. This conservation of person is also demonstrated materially. For example, colored liquid in a shallow pitcher is conserved as the same quantity when it is poured into a tall tubular pitcher, as are a row of coins whether spread out or piled together. These achievements indicate that there are shifts in the child’s mental strategies available to assimilate new tasks in formal elementary education and logic. These new strategies permit comprehension and production of sequential relationships in story lines and also the integration of stories into larger generalized categories above and beyond the immediate task orientation.

An alternative to the Piagetian perspective, that is focus on a uniform change in children’s problem-solving skills at each stage, is one that examines the set of strategies children use for problem solving, as well as the changes this strategy undergoes with development. Trial-by-trial analyses have shown a great deal of variability in the approaches of children to problems of arithmetic, spelling, and moral reasoning, which are the classical domains that have given rise to stage theories (Siegler et al. 1996). For example, trial-by-trial analysis of the performance of 5-year-olds in a number conservation task showed that they make judgments on the basis of not only the relative length of the rows, but also the type of transformation made, and the results of counting (Siegler 1995). The influence of this cognitive variability on the process of learning is largely determined by the efficiency of strategy selection. The school-age period has been the major focus of research on the adaptiveness of the strategy that children choose. An adaptive approach might be to use a fast strategy when speed is contextually important and the slower backup strategy when accuracy is emphasized.

Age and experience are accompanied by acquisition of new strategies, changes in use of existing strategies, improvements in execution of strategies, and more adaptive choices between strategies (Lemaire and Siegler 1995). Generalization of strategies to new problems is a slow process, specifically in cases when other effective strategies exist (Kuhn et al. 1992, Siegler and Jenkins 1989).

Neopiagetians have challenged the strict sequential notions that mark the original model of Piaget. However, they do not take issue with the idea of the constant set of transformations and the increasing capacity for new mental strategies and varying forms of logical integration that are characteristic of this period. Kendler and Kendler (1962) showed that children of age 7 years can solve particular cognitive experimental sequences that demonstrate that they now use integrative reasoning, insight, and inferential behavior. White (1965) offered a comprehensive summary of the discontinuity and developmental achievements of middle childhood, recommending that the hierarchical arrangement that was suggested by Werner (1957) on theoretical grounds was valid. These new cognitive strategies are also geared toward change in language representation. White described the new capacity to maintain a constant orientation toward an invariant dimension even though the surroundings are varied. These new modes are not simply epigenetic in their organization based on cumulative achievements; they are indeed new skills based on new integrative cognitive structures.

The time line in Figure 10–3 presents cognitive development from age 6 to 12 years.

**Emotional Development**

If we look at emotions as native dispositions represented by the seven emotions of Darwin, we observe that the emotional life of infants and toddlers is reciprocally modulated in relation to the caretaking environment by feedback behaviors defined as *social referencing* (Klinnert et al. 1986). Mahler and associates (1975) described the checking
and “refueling” that take place during development in 2–3-year-olds. Two lines of investigation address the precursors to emotional development in latency, which are significant. One pertains to the follow-up studies on security of attachment at 18 months using the strange situation paradigm of Ainsworth et al. (1978). The other line of research concerns temperamental variation in early childhood and its predictive value for emotional modulation and expression during middle childhood. Sroufe and Fleeson (1984) showed that by the time securely attached children are 8, 9, and 10 years old, they are more socially adaptive and have better peer interactions (Sroufe et al. 1999). However, the earlier measure does not guarantee good outcome, as there are many significant transactional social and familial factors that mitigate development.

The work of Chess and Thomas (1984) has already been cited with regard to the continuities and discontinuities that they found in the difficult child. Such continuities only account for a small amount of the variance of later outcome.

Although epidemiological studies show that depression is not highly prevalent in middle childhood, it is now clear that major depressive disorders do occur (Puig-Antich and Rabinovitch 1986, Kovacs 1989). There is a rising rate of emotional disorders in early adolescence, followed by a steep, continuing rise of incidence of these disorders into late adolescence. Kagan et al. (1989) showed that early behavioral and emotional inhibition often evolves in middle childhood as anxiety disorders that match parental anxiety and may reflect a genetic origin. This method of tracking the extremes from early childhood suggests a useful research strategy for the study of the genetic determinants of behavior.

The modulation of emotions by new cognitive structures was thought to occur as a result of a signal of anxiety triggered by perceived dangers concerning bodily harm. This was thought at times to take the form of behavioral separation anxiety (Freud 1926). In the later forms, school avoidance and school reluctance may be the major features of manifest anxiety seen in the clinic (Shapiro and Jegede 1973). The idea that the modal latency-age child is more emotionally contained than the exuberant preschooler has not been found across cultures, just as the postulated diminution of sexuality was shown to be culturally bound (Ford and Beach 1951). These findings notwithstanding, Ramsey (1943) found that rates of masturbation in boys rose from 10% at age 7 years to more than 80% at age 13 years.

There are also suggestions that development provides a trigger for gene expression at various times in childhood. Thus, it may not be only the condition of changing dependency that is central to the emergence of mood disorders. Support for the discontinuity model is provided by the observation that children with the earliest expression of major depression seem to have a different course from those with a later onset (Kovacs 1989). It is during this period of middle childhood that peer socialization takes on new significance, becoming an additional boost to feelings of approval and self-esteem. At a biological level, the progressive maturity of the dorsolateral frontal cortex places the brain under the most forceful modulating effect, guaranteeing less impulsivity.

**Sociocultural Development**

Erikson (1963) provided an epigenetic model that maintains that prior stages have strong influences on the later stages of development. His model contrasts with discontinuity
models insofar, as traversing a stage-phase boundary does not permit the developing child to leave behind the “faults” that characterize their previous stage. By contrast, the discontinuity model offers the possibility for reorganizations without the necessary continuing major impact of earlier dynamisms. Sociocultural behavior of middle childhood has been described most extensively for middle-class US culture, although some poor and inner-city populations have been studied. Many behaviors of middle childhood can be construed as new aspects of the socialization process that is fostered by schools, community involvement, and the gradual distancing from the family.

Children of this age form clubs that mimic parental social groups. The “natural club” of the school-age child borrows from larger societal forms, but, unlike the Cub Scouts or Brownies, it does not accept the rules offered by adult structures. The rules are provided by a new oligarchy of strong-minded children experimenting with leadership, demanding many CEOs and fewer workers.

Secrets and collecting are important. The tendency to collect everything from bottle caps to baseball and Pokemon cards has led to widespread advertising that stimulates peer pressure. More sports-minded children can become devoted to collecting enormous cadres of statistics regarding their favorite sport. Children who may not perform as well in athletics often turn to collecting. If you cannot hit home runs, you can at least have at your fingertips the names and records of baseball heroes to impress your peers. The traditional image of the child emptying pockets stocked with pieces of string, small stones, keys, and other personal treasures is typical of this period. Stamp collecting and coin collecting have their origins and fascinations during this period and lead to increased knowledge that parallels and enhances the learning of geology, geography, and history. Newer collections based on current fads bring the child into his/her peer culture. Devotion to particular forms of attire also becomes clearly delineated at this point, as social consciousness rises with respect to what is “in” and what is “gross.” Children may also become rather cruel toward each other with regard to teasing or “tacky” name-calling. Particular styles of dress become associated with idealized figures and are treasured with regard to early crushes and devotions that become paramount in adolescence.

The concept of a joke can be appreciated in a new way during middle childhood, as “knock–knock” jokes are replaced by more pointed stories with clear punch lines. The school-age child can be reduced to hysterical laughter by bathroom humor. Explicit virtuoso performances of burps or flatus are exceedingly popular. The titter that is created by these demonstrations sometimes evolves into belly laughs that adults find silly or inappropriate.

Mastery of the body is also a prominent theme during latency. A latency-age child may shoot baskets or practice the piano for hours. Boys may endlessly grease and pound a new baseball glove to make the perfect pocket. Girls of this age are likely to dance or exercise for hours on end.

The unisex friendships of this period lead to a number of avoidant practices that emerge in groups. The frequent culturally determined “cooties,” a mythical contagious disease that comes from touching a person of the opposite sex, serve the function of maintaining a safe sexual distance. The notion of contamination by those who are sexually active and the reaction formation of expressing disgust at the thought of kissing and turning away from romantic scenes in films are prominent behaviors during this period. The tendency to establish same-sex groupings becomes more pronounced at ages 7 and 8 years.

Shame serves as another social regulator. Any suggestion of romantic attachment or interest in someone of the opposite sex may raise titters among latency children, with embarrassment as a deterrent. During this time, boys and girls are trained to “one-up” each other, with the threat of potential humiliation. Skill at sports, dance, or other physical prowess often leads to increased socialization and enhanced self-esteem and competence during middle childhood. Peers have little tolerance of boys who deviate from clear gender role play. Anthropological investigations show that most cultures provide rituals that accompany the transition to adult male status and that preparation for these rituals begins during middle childhood (Gillmore 1990).

Anthropologists also have indicated that in cultures other than middle-class US culture and also within ghetto cultures, sexuality is not dormant. Variations in latency are determined by aspects of permission and prohibition within each culture. Erikson (1963) described the variations in Native American and urban US cultures. Maccoby (1990) conducted studies modifying our notion of the latent period in middle-class US samples. Nonetheless, although some cultures do not appear to show a latency, most take some notice of prepubertal status, because it is during the next phase that most of the rites and privileges of young adulthood are bestowed by ceremonial or ritual behaviors, permitting children to enter into adult practices. It is a time when respect for parents and larger cultural institutions begins to be solidified.

**Moral Development**

Moral development may be looked at as an independent line that describes the capacity of the child to act in accord with conscience and moral imperatives rather than egocentric values. The belief that the superego was formed as a residue of identifications and drive resolution at the end of the oedipal stage has been modified by new evidence of internal control in accord with the development of moral injunction during the preschool years (Buchsbaum and Emde 1990). Nonetheless, the internalized “oughts” and “shoulds” of the latency period represent a new cognitive advance and a new capacity to contain emotions that sometimes lead to conflict and/or exceedingly rigid moral restraint. It is a period when an 8-year-old can turn on his or her father for the slightest moral infraction for the sake of obeying the code. It is a time when children receiving religious education chide their parents for not following the rules and not attending church. Latency-age children frequently recognize parental hypocrisy preceding the more widely recognized phenomenon of adolescent protest. There is a tendency for good and bad to take on absolute valence that allows little room for shades of gray.

Gilligan (1982) has found in naturalistic observations that the quality of mercy that was involved in human interactions and concern for interaction is more characteristic of girls than of boys. Boys in contrast tend to seek blind justice.

Piaget (1948) studied how children use varying systems of rules. He observed boys playing a game of marbles and,
feigning ignorance, asking how the game worked. He con-
cluded that there were stages in the acquisition of moral judg-
ments. From 4 to 7 years, children appear egocentric because
they are not able to take another’s perspective. They follow
a fluctuating set of rules that is governed by inner dictates.
From 7 to 11 years, rules are followed more carefully. Only
at 11 or 12 years are absolute rules scrupulously demanded
in rule-governed games. He also found that 5–9-year-old
children believe that rules are inviolable, originating in some
obscure absolute authority. However, 10- or 11-year-old chil-
dren question this and show the ability to consider social
contracts mutable. Piaget similarly studied ethical questions,
showing that younger children believe that if something bad
is done, punishment must follow. In contrast, older children
take motivation into account, asking what the individual
meant to do. Children’s sense of fairness also begins to evolve
during this time, and the idea of “it isn’t fair” emerges. Colby
et al. (1983) and Colby and Kohlberg (1987) used Piagetian
techniques to study the response to moral dilemmas at vari-
ous ages.

The six stages of moral development described by
Kohlberg were believed to have an invariable sequence, mim-
icking Piaget’s scheme (Table 10–1). The first two stages
were called preconventional morality. The vast majority of
10-year-olds were found to be at this level. The first stage is
egocentric, with the rights of others being irrelevant. Action
at this stage is deferred to avoid punishment. The second-
stage child acknowledges that other people have interests
too, but the child’s own interest prevails at this level. Con-
ventional morality, stage 3, involves being good by living up
to what people generally expect of one. By stage 4, the child
is oriented toward maintaining the social norm. At postcon-
ventional morality, a child may consider questions from both
a moral and a legal point of view, even acknowledging that
there might be conflict. At stage 6, there is consideration of a
universal moral principle of justice that may override human
law. Walker (1989) found some support for Kohlberg’s
sequencing of stages but not for the existence of significant
differences between the sexes. Smetana and colleagues (1991)
studied third, sixth, and ninth graders and found little support
for Gilligan’s differential between boys and girls, comment-
ing that there were few sex differences between interpersonal
considerations and issues of justice, while the precursors of
moral judgment are already present in 3-year-olds; accord-
ing to Buchsbaum and Emde (1990), there is a consolida-
tion of moral rules during latency marked by excessive
rigidity, which becomes more broadly conceived in light of
reason and the human condition as adolescence proceeds.

| Stage 1 | Might makes right (punishment and obedience orientation) |
| Stage 2 | Look out for number one (instrumental and relativist orientation) |
| Stage 3 | “Good girl” and “nice boy” |
| Stage 4 | Law and order |
| Stage 5 | Social contract, legalistic |
| Stage 6 | Universal ethical principles |

Figures 10–4, 10–5, and 10–6 present time lines for emotional, moral, and social development in 6–12-year-olds.

**Risk and Protective Factors**
During the school-age years, the prevalence of psychiatric disorders begins to rise. Prepubertal depression is associated with a worse prognosis (Kovacs 1989). Attention-deficit hyperactivity/disorder increases in prevalence as school demands increase. Separation disorders emerge as schooling away from home becomes mandatory (Shapiro and Jegede 1973). Children who are prone to conduct disorders show their symptoms more prominently when new demands of school are introduced. The onset of psychopathology is linked to “turning on” genes. This process must be understood within the context of risk and protective factors. Sameroff and Chandler (1975) examined the notion of a continuum of reproductive casualty and found that social influences become more significant among the factors that account for the expression of disorder. If problems related to early biological hazards are considered, the school-age child’s problems are better accounted for on the basis of sociofamilial factors than perinatal insult. Specifically, the status of growing up in extreme poverty, in a single-parent family, and being subjected to child abuse is more highly associated with the onset of psychopathology than the occurrence of early anoxia, prematurity, or complications of delivery. Early positive influences must also be considered. For example, programs such as Head Start seem to have protective influences later in development (Consortium for Longitudinal Studies 1983).

**Developmental Psychopathology**
The middle years are marked by a new availability of skills and coping mechanisms, permitting children to expand
Understands that people can have multiple roles
Likes some social routines
Interested in secrets, collecting, and organized games and hobbies
Off-color humor emerges
Primarily unisex friendships
Explains actions by referring to events of immediate situation
Redefines status relationships with friends
Same-sex groupings prominent
Punchlines emerge in humor
Focus on peoples’ physical appearances as opposed to their personality dispositions
Adoption of group’s values, speech patterns, and manners
Strong peer group affiliation
Rise in social consciousness with respect to what is “in”
Increased self-regulation
Best friends rise in importance
Understands that emotions have internal causes
Recognizes that people can have conflicting feelings and can sometimes mask true feelings
Relates actions to personality traits and feelings
Sees friends as people who understand each other and share thoughts and feelings

Their achievements when appropriate support systems are available. The emergence of psychopathology can be understood from the perspective of factors that enhance or inhibit these new roles or skills. It is widely accepted that developmental psychopathology is the result of multiple causes (Cicchetti and Cohen, 1995). The origins of psychopathology are best understood by examinations of both successful and unsuccessful adaptations, always maintaining that psychopathology occurs in the developing organism. Anxiety disorders are of the most prevalent form of emotional psychopathology in school-age children (Costello et al. 2003, Ford et al. 2003). Many cognitive childhood disorders have at their core some deficit in the suppression of inappropriate thoughts or behaviors.

There are factors that predispose children to developing anxiety disorders and others that are protective. Neuroticism, behavioral inhibition, and disgust sensitivity are genetically based factors thought to play a role in the pathogenesis of childhood anxiety disorders (Muris 2006). Experiential factors include negative life events and family dynamics (Dadds and Roth 2001). Indeed, early attachment relationships have been shown to influence the pathogenesis of childhood anxiety disorders. Effortful control has been cited as a protective factor. This is defined as the ability to effectively regulate thoughts and behavior for goal-appropriate action. Interestingly, several disorders that emerge during the school-age years are characterized by disruptions in this effortful control.

Children with attention deficit hyperactivity disorder have problems with attentional focus, distractibility, and impulsivity (Barkley 1997, Casey et al. 1997a, 1997b, Trommer et al. 1991). In Tourette syndrome, children have difficulty suppressing either movements or vocalizations (Leckman et al. 1987). Obsessive compulsive disorder is described as an inability to suppress intrusive thoughts or behaviors, and in childhood-onset schizophrenia children cannot control attending to inappropriate thoughts and information (Asarnow et al. 1995). While the specifics of the disorders are different, all share an inability to override irrelevant thoughts or behaviors, and all have been shown to involve the basal ganglia and the prefrontal cortex, which is known to be maturing during middle childhood.

The tasks and challenges of the school-age period represent an amalgam of cognitive and emotional maturation. Developmental course can be enriched or impoverished by the environment. Success in mastering environmental challenges during the school years provides an important foundation for the challenges of adolescence.

Sexual dimorphism supported by the strong effect of societal norms is at its height in this period. Postpubertal
sexual behaviors are cultivated during latency. As Erikson (1963) noted, this is a period of industry in which tools for the intellectual work to come are forged, but prepubertal fantasy and sexual role definition are also silently cultivated. Thus, areas such as sexual role, identity, and partner choice are significantly influenced by the prior period of latency.

Clinical Vignette 1

This case demonstrates the interplay between biological predispositions and current stressors, which permits the expression of emergent pathological conditions in the middle school years. Josh was a vulnerable infant who had suffered seizures and had a restrictive temperament. His mother's panic and his parents' separation augmented his rising anxiety. Unfortunately, his anxiety was aggravated by the anxiety that his mother experienced.

Clinical Vignette 2

Josh, a 7-year-old boy, was in second grade for about 1 month when he had a mild febrile illness that kept him at home for 2 days. Because the next day was Friday and his mother was at home for the day, she permitted Josh to recover over the long weekend. He and his 5-year-old brother Kevin played well. His mother seemed quite pleased that the three of them had these days to spend together.

On Monday morning, Josh did not want to go to school. He protested that his stomach and head hurt. He also said that he was worried that his mother would be hurt at her job. His mother worried that Josh was ill again and decided to stay home with him. Within 40 minutes, Josh seemed content and happy, but he was reluctant to let his mother out of his sight. However, he promised that he would go to school in the morning. The next day he was again reluctant to go to school and wept bitterly as his mother became increasingly anxious and angry. This pattern continued each morning throughout the week. Consequently, his mother was advised to obtain a child psychiatric consultation.

The development history revealed that Josh's mother separated from his father when he was 3 years old. Although his father had been conscientious in his visitation, there had been an alteration about child support between his parents and unpleasant accusations had been exchanged. Josh overheard these arguments and became progressively worried about his mother and his own safety. Josh's mother had suffered from panic anxiety for many years. She found it difficult to maintain social relationships and was generally fearful about her children when she became anxious about their safety.

Josh was a normal full-term infant, but he had developed an elevated bilirubin level that required ultraviolet light treatment. He had two febrile seizures before he was 18 months old and was temporarily given phenobarbital. His mother had frequent otitis media and was described as “slow to warm up” child with a cautious restrictive temperament. His motor and language landmarks were all well within normal limits, but when he began kindergarten, he took longer to get used to the daily separations than his peers. Otherwise, he was a bright, imaginative youngster who did well in one-on-one interactions.

Adolescence is the developmental phase that spans the transition from relatively complete childlike reliance on parents to nearly complete self-reliance for the management of one’s own life (Kett 1997). Although the term adolescence did not have its current meaning before the middle of the nineteenth century, young people have always had to make the transition from being considered dependent children to being regarded as independent adults. This transition occurs in almost all societies. Although the Bible, St. Augustine, and Shakespeare have commented on the joys, dangers, and sorrows of this transition period, it has been studied only in this century (Hall 1882). In premodern times, the passage to adulthood was demarcated by a puberty rite. Before enacting the rite, one was a child; after completing it, one was an adult. This ritual was far more explicit than it is today. The contemporary steps include a variety of experiences such as first communion, bar mitzvah and bat mitzvah, paying the full cost for social events and being granted certain privileges such as driving legally, consuming alcohol, voting, and performing military service.

It appears that different societies have different time frames for this transition, and even the same society is likely to modify the steps and ages over time. The clearer and narrower a society is in its definition of and expectations for adulthood, the more smoothly the child passes through adolescence. Greater freedom fosters greater latitude for the young person and generates greater confusion about what constitutes an adult to the individual, his or her parents, and society.

The changes during adolescence span physical, psychological, and emotional domains. Near the time of puberty, there is a sudden increase in the size of hands and feet, height, body hair, and genitalia. Boys experience a voice change and an increase in muscle mass; girls develop breasts and begin menstruation. Thinking also changes. Particularly for boys, sexual thoughts become more common, explicit, and intrusive, and there is an upsurge of aggressive feelings and urges. However, the timing of these changes is highly variable.

Girls typically enter puberty about 2 years earlier than boys, but for both sexes the age of onset of puberty is highly variable. Some girls begin their growth spurt as early as age 9 or 10 years and are physically adults 4 or 5 years before late-developing boys even begin their pubertal changes. Consequently, one contribution to the emotional chaos of this age group stems from the widely divergent physical and emotional development of its members. A seventh- or eighth-grade classroom is filled with ever-changing strangers, and teachers must cope with the diversity of physical and emotional maturity within the constraints of the same curriculum, textbooks, sports matches, and social events. Not only is there a disparity in appearance among students, but how individual students feel about themselves is often in flux as well. It is not unusual for a young adolescent to feel and behave maturely and independently in one context and then childishly and dependently in another.

It is useful to divide adolescence into three overlapping biopsychosocial phases (Table 11–1) that are epigenetic in that each leads to the next. However, there are wide variations among individuals with regard to the age at onset and duration of each phase. On average, girls precede boys into each phase. Early adolescence typically begins near the end of grade school or the beginning of middle school. This phase is characterized by a growth spurt, beginning development of secondary sex characteristics, greater social separation from parents and family, and greater affinity with peers. These shifts are often manifested by changes in attitude, clothing, and hairstyle. It is common for adolescents and their parents to harbor doubts about whether the changes in body and thought are normal, and reassurance is often sought from the family physician or pediatrician about these fears. Masturbation begins or becomes more frequent, and although there may be strong romantic crushes on older and unobtainable persons, the peer group...

remains predominantly unisexual. Concerns about possible homosexuality are common, especially for boys.

Midadolescence typically occurs during the middle teenage years, and sexual experimentation between teenagers usually begins at this time. As the individual gains a more consolidated and surer sense of himself or herself, there are more serenity and less uncertainty about sexual orientation. Late adolescence, which typically takes place during the late teens, is a time of assuming adult responsibilities and perspectives rather than focusing on earlier conflicts related to dependency. This requires decisions about school, work, leaving home, and romantic relationships and commitments.

Table 11–2 shows a set of tasks that are accomplished by psychologically healthy adults (Schwalter 1995). These tasks are seldom fully completed by the end of the teenage years or even in the early 20s but represent key development objectives for this period.

### Historical Perspectives

Kett (1977) claimed that "every generation of intellectuals since 1820 has been convinced that an acceleration of the velocity of social change..." but it seems clear that the industrial revolution of the late nineteenth century was crucial for the structuring of adolescence and has had a calamitous effect on youth. Kett noted that although Hall originally conceived the age of adolescence as extending into the early 20s, his educator followers shifted the time frame of adolescence to be coincidental with secondary school. Eventually, adolescence became synonymous with the years between the end of primary school and the leaving of school in the middle to late teens, although this is artificially too brief.

Sigmund Freud (1953) in *Three Essays on the Theory of Sexuality* declared that puberty was not when sexuality emerged. Rather, humans experience an active and varied array of sexual wishes and feelings from the time of infancy. Freud believed puberty was the time when the genital zone attained primacy. He proposed that this occurred when the earlier oral, anal, and phallic sexual instincts come under the sway of the reproductive function. Psychoanalysts have debated the preeminent importance of the first 3 years of life, the oedipal period of about ages 4–6 years, and the period of adolescence for adult development.

Anna Freud (1946) in *The Ego and the Mechanisms of Defence* focused on the adolescent years. She described the mind's defense mechanisms and highlighted their use for adaptation during adolescence.

Blos (1962) stressed that the two primary and interacting developmental themes for adolescents are the revival of the Oedipus complex and the need to disengage from the close childhood-based ties to parents. Blos proposed that a major problem arises when the adolescent withdraws emotionally from the parents and from the parents' values. This leaves the adolescent bereft of accustomed moral underpinnings just at the time when sexual and aggressive fantasies and urges are greatest.

Psychoanalysts emphasized that adolescence was a time of *Sturm und Drang*— storm and stress. By the 1960s...
and 1970s, research began to indicate that emotional upheaval was not necessary for a successful transition from childhood to adulthood. Offer (1969) and colleagues (Offer et al. 1989) studied high school students in Chicago and reported that a large majority displayed relatively little turmoil. Although these youngsters became more attached to and influenced by peers, they were still most powerfully influenced by their parents. Rutter and colleagues (1976) reported on studies demonstrating that major turmoil during adolescence was not a developmental necessity. Rutter believed that adolescents often feel more misery than is noticed by parents and other adults but that the degree of turmoil and its psychiatric importance had been exaggerated in earlier clinical reports. This view opened the way to more modern, empirically driven view of cognitive and emotional development during adolescence.

**Conceptual Framework**

The conceptual framework draws on concepts of continuity and linkage. The sections of this chapter consider biological, cognitive, social, and moral development as separate pathways, but each has its inception in childhood and merges imperceptibly into adulthood. Thus, development can be viewed as a continuous process that begins with the absolute helplessness and dependency of an infant and proceeds toward the capacity to fulfill one’s own requirements and to effect propagation of the species. At any one point there is continuity, connections with the previous and succeeding points on this continuum. For example, adolescents’ first experiences with members of the opposite sex are influenced by prior experiences with same-sex relationships and sex-role identifications. These experiences with members of the opposite sex are influenced by prior experiences with same-sex relationships in childhood and in turn may affect later decisions about their adult choice of a sexual partner.

Moreover, this continuum is composed of a number of simultaneous developmental events that occur at different levels in different domains (Figure 11–1). These events and domains are said to be linked. That is, they are related to one another and influence one another but are not epigenetically dependent on one another. At any one moment, an individual may be more mature in one domain than in another. Yet the interplay of these domains affects overall development in a fundamental way. For illustration, one domain, such as heightened motor skills, may interact with a separate domain, such as enhanced cognitive abilities, resulting in improved athletic performance. Increased strength and reflex speed do not activate the ability to perceive weaknesses and form a strategy for defeating an opponent. However, when they are combined, the player may be more victorious on the field. Subsequent varsity success may affect self-image and peer social status.

At each arbitrarily defined phase there are tasks, responsibilities, and pressures that are particularly characteristic of that time. Across individuals, no matter how different the sources of these demands and pressures may be, the conflicts of a particular developmental phase are remarkably similar. Thus, it has been argued that adolescence recapitulates the struggles of toddlerhood, but at a different level (Blos 1962). One similarity between these two developmental phases is the conflict between wishes for self-sufficiency and the recognition that one’s capacities are not yet at a level that permits these strivings to be fulfilled. However, major differences exist. The limitations of adolescence are derived from much broader realms than those of the toddler. The immediate source of limitations on strivings for adulthood may be physical, familial, cultural, or social. Moreover, the pressures on adolescents stem from both internal and external sources. Examples of internal sources are sexual urges and capacities, longings for self-sufficiency, awareness of new capabilities, and feelings of dependency and uncertainty. Some examples of external sources are the tacit requirements for being a responsible member of society, expanded parental expectations, and more intense and complex peer pressures that exert demands to “fit in.”

The negotiation of these conflicting pressures is determined by the interplay of biological, social, familial, cultural, and psychological factors. Although there is continuity in some of these domains, there are also discontinuous events. Falling ill with a chronic viral disease, suffering a traumatic physical injury, experiencing war, living in a period of economic decline, or experiencing sudden parental death may not be related to what has come before but certainly influences what follows. Models of development cannot take these more random events into account, but the factors that influence successful accommodation to them are probably rooted in the same elements that promote optimal adaptation to the predictable conflicts of development. There is a bias in the assumption that these unpredictable events typically exert an adverse effect on development. Positive developmental consequences of unpredictable events are also possible.

**Biological Development**

Adolescence is related but not identical to puberty. Puberty is a biological event, whereas adolescence is a period designated by society. The biological changes of puberty may predate or may not have occurred by the age that society has designated as the definition of adulthood. Puberty originates from the Latin *puber*, which refers to “being of marriageable age.” This linguistic link implies an emerging capacity for reproduction. There is a prominent implication of the primacy of biological capacities in the understanding of this stage of development. These biological changes are both the most rapid and the most striking of the physical changes that the body experiences after infancy. By the end of this stage of development, the body has reached adult stature and sexual appearance. Biological changes include

![Figure 11-1 Interplay of developmental domains.](image-url)
maturation of sexual organs and capacities, cardiovascular function, body composition, height, and weight. A time line of biological development from age 13 to 18 years is presented in Figure 11–2.

The development of secondary sex characteristics in both sexes has been well documented (Marshall and Tanner 1969, 1970). Although photographs imply that staging development is an objective process that be accomplished with great accuracy, one should understand that breast or testicular growth are continuous and placement into each stage is subjective (Sun et al. 2005).

Marshall and Tanner (1969) suggested five stages of pubic hair development (pubarche). In both sexes, stage I has no pubic hair. The chain of events leading to pubic and axillary hair growth (adrenarche) is separate from production of gonadal steroids, and this accounts for some children developing hair growth prior to breast budding or testicular enlargement. Thus, pubic hair stages may lag behind breast stages in girls (Figure 11–3) and genital development in boys (Figure 11–7). Andrenarche begins with production of dehydroepiandrosterone sulfate (DHEA-S) in the adrenal zona reticularis beginning at the age of 6 years and peaking at the age of 25 years (Achus and Rainey, 2004). The mechanism for the onset of these events remains obscure, but circulating levels of insulin (Slyper 2006), leptin (Garcia-Mayor et al. 1997), and ACTH may be important (Taha et al. 2005), as well as inhibition of 3β-hydroxysteroid dehydrogenase (Gell et al. 1998). Circulating DHEA-S is converted locally to testosterone and dihydrotestosterone in apocrine glands, leading to body odor, and hair follicles, giving way to production of coarser hair in the axillae and pubic region (Achus and Rainey, 2004). In girls, stage II hair development is characterized by straight or only slightly curly hair that has little pigmentation and primarily appears on the labia (Figure 11–5). These changes arise at an average age of 9.4–10.6 years—recent figures reflecting earlier onset than the previous 11.9 years (see Figure 11–6) (Sun et al. 2002). Stage III shows the characteristically dark curly hair that spreads from the labia over the mons. By this time, the mons itself has gained in size as a result of increased fat deposition. Stage IV shows the entire mons overspread by thick dark pubic hair that does not yet extend as far as the medial aspect of the thigh. Stage V shows the typical adult distribution, which includes the areas of the medial thigh (see Table 11–3 and Figure 11–5). In girls, axillary hair develops during the later portions of stage III or during stage IV and appears at an average age of 13.2 years (Wheeler 1991).

Male pubic hair development, under control of adrenal androgens (see Figure 11–5), may not be synchronous with genital development (Marshall and Tanner 1969). Stage II is characterized by sparse growth of slightly pigmented
straight hair primarily at the base of the penis. Stage III corresponds to hair that is dark, curly, and distributed over the mons. Stage IV hair is spread over the mons but does not reach the medial aspect of the thigh. In stage V, hair growth has reached the adult distribution (Table 11–4). For boys, the average time from the emergence of the first pubic hair to reaching the adult pattern is 2.7 years (Wheeler 1991).

In girls, roughly 50% will have thelarche and pubarche at the same time (Biro et al. 2003). In a study of white females, among the other 50%, 60% had the onset of puberty with the appearance of thelarche, and 40% had the onset with pubarche (Biro et al. 2003). Whether one exhibited the thelarche or pubarche pattern was not associated with differences in the age of onset of menarche. However, those who showed thelarche before pubarche exhibited higher body

mass indices (BMIs) and proportion of body fat (Biro et al. 2003). They also showed greater risk of obesity in adult life (Garn et al. 1986). Before these observable changes, ovarian secretion of estradiol and progesterone produces an increase in vaginal length and cytological transformation of the cells in the vaginal lining (Wheeler 1991).

Breast development (Figure 11–3) follows a predictable sequence under the influence of ovarian estradiol and progesterone production. Asymmetrical growth is common (Marshall and Tanner 1969). The average age for the onset of breast development (thelarche) has required revision with more comprehensive epidemiological methods (Sun et al. 2002). A previous figure was 11.2 years, but the age of thelarche has declined and newer estimates recognize considerable racial and individual variation (Sun et al. 2002). A more accurate estimate for phase II is probably 9.5–10.4 years old (Sun et al. 2002) (Figure 11–6). Stage I consists of only a raised papilla. In stage II a breast bud is visible, with enlargement of the areola. In stage III, there is an enlarged breast without separation of the contours between the areola and the breast itself. Stage IV is defined by further enlargement and projection of the areola and papilla to form a secondary mound above the level of the breast. In stage V, there is an adult breast contour with elevation of the papilla only (Table 11–3; see Figure 11–3).

Typically, within 2 years of the onset of breast development menarche is attained (see Figure 11–4) (Zacharias and coworkers 1976). The average age for menarche is 12.4 years (Sun et al. 2005, Chumlea et al. 2003), and the range is 10–14 years. This is influenced by race. On average, onset is earliest in non-Hispanic blacks, slightly later in Hispanic girls, and latest in non-Hispanic whites. Across all races, 10% of girls will have onset of menses by an average age of 11.1 years and 90% will have menarche by 13.8 years of age (Chumlea et al. 2003). After menarche, from 2 to as long as 5 years, menstrual cycles are typically anovulatory (Wheeler and coworkers 1976). The average age for menarche is 12.4 years and 90% will have menarche by 13.8 years of age (Chumlea et al. 2005), and the reported average age of spermarche is 14.3 years (Wheeler 1991). The sequence of maturational events in girls is shown in Figure 11–6.

In nearly all boys, the onset of puberty begins with testicular enlargement. Enlargement is a consequence of cellular proliferation of the seminiferous tubules caused by rising levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (Odell 1995). Prepubertal testes respond to a variety of tropic substances with production of testosterone. The appearance of sustained increases in levels of circulating testosterone lags behind measures of testicular volume, implying separate mechanisms in the induction of testosterone secretion by Leydig’s cells and the proliferation of seminiferous tubules. Spermatogenesis occurs after the increase in testicular volume. Obtaining an estimate for spermarche has proved difficult, as it may be based on the average age of conscious ejaculation or presence of sperm in urine samples. Different methods yield very different results, leaving the age of onset uncertain. The reported average age of spermarche is 14.3 years (Wheeler 1991). The stages of male genital development are based on testicular size and penis length and are associated with increases in serum testosterone levels (Marshall and Tanner 1970) (Figure 11–5). Stage I is characterized by testicular

length less than 2.0 cm. Stage II is defined by testicular length between 2.5 and 3.2 cm and is usually associated with scrotal thinning. Stage III reflects growth of the penis and lengthening of the testis to between 3.3 and 4.0 cm. Stage IV is characterized by lengthening of the penis and testicular enlargement to 4.1–4.9 cm in length, with darkening of the scrotum. Stage V corresponds to adult testicular size (greater than 5 cm). Usually, the left testicle hangs lower in the scrotum and the right testicle is larger (Odell 1995). In boys, onset of pubic hair growth ranges from age 8.3 to 12.8 years (Sun et al. 2002, Lee et al. 2001).

Male axillary and facial hair growth is affected by testosterone and is not tightly linked to the appearance of other sexual features. The typical adult pattern of facial hair occurs within 2 years of Tanner’s stage II pubic hair development (Wheeler 1991). Male facial hair emerges at an average age of 14.9 years at the lateral aspects of the lip and moves medially (Lee 1980). Chin hair usually appears last. The deepening of the male voice is a consequence of enlargement of the larynx and thickening of the vocal chords. These changes are under the control of testosterone and its metabolites and correspond to the male growth spurt. The sequence of maturation events in boys is shown in Figure 11–7.

Puberty changes the distribution of muscle, fat, and water in the body. In girls, muscle mass continues to develop until menarche and then declines. In boys, muscle mass, which is under androgenic stimulation, develops throughout adolescence and is accompanied by increases in bone density. In girls, fat distribution continues throughout puberty and by the end of puberty lean body stores of fat are double those of boys. In boys, intracellular water increases during puberty to 39%, whereas in girls it decreases to 29% (Wheeler 1991).

A variety of factors affect the onset of puberty, including, but not limited to, genetic endowment, adequate nutrition, and general health status, as well as environmental factors such as altitude, and physiological factors such as prolonged heavy exercise. There may also be an association between deprivation of exposure to light and earlier onset of puberty. Girls who are blind from birth or who reside in extreme latitudes where there is little light for protracted periods may have earlier onset of puberty on average (Cardinali and Vacas 1984). The importance of nutrition for the onset of menarche is highlighted by data that suggest that menarche in America now occurs more than a year earlier than it did in the mid-nineteenth century (Wheeler 1991, Brook and Hindmarsh 1992).

Long before body changes appear, there are gradual increases in levels of circulating FSH and LH, which are produced in response to secretion of gonadotropin-releasing hormone (GnRH) (or leutinizing releasing hormone (LHRH)) into the portal pituitary circulation. GnRH is secreted in a nocturnal circadian rhythm in pulses (Grumbach 2002). Throughout childhood, GnRH, LH, and FSH follow a steady nocturnal pulsatile pattern (Boyar 1978). As adolescence approaches, the rate and amount of secretion of GnRH increase and the pattern changes to day and night pulses (Boyar 1978). The switch that produces increasing LHRH pulse frequency and amplitude appears to be “turned on” by inhibition of gamma aminobutyric acid (GABA) and increased release of glutamate leading to activation of N-methyl-D,L-aspartate (NMDA) receptors (Grumbach et al. 2002). As much as 2 years before increases in circulating gonadotropins, circulating adrenal androgenic hormones—dehydroepiandrosterone and 17-ketosteroid—increase in both sexes. As puberty nears, LH and FSH levels increase sharply. LH in boys increases the secretion of testosterone, which reaches adult levels within a year.

Both growth hormone (GH) and gonadal hormones are needed to initiate and sustain the adolescent growth spurt. GH is one of the most important influences on height and may be excreted at significantly higher levels in taller children than in their smaller peers during childhood (Brook and Hindmarsh 1992). The secretion of GH is under the control of GH-releasing hormone and somatostatin. In addition, estrogen, thyroxin, and glucocorticoids affect GH secretion. The timing of GH spikes is dependent on diminishing levels of somatostatin, and the amplitude of the GH spikes is directly related to GH-releasing hormone levels. GH-releasing hormone also appears to have a role in facilitating GH gene transcription.

The adolescent growth spurt depends on GH levels. Throughout childhood, GH levels are similar in both sexes. Under the influence of rising levels of gonadal steroids and GH, the growth spurt appears earlier in female development. The female growth spurt typically occurs during breast stages II and III, whereas the male growth spurt occurs during genital stage IV (Wheeler 1991, Odell 1995, Brook and Hindmarsh 1992). The circadian timing of GH secretion is the same in both sexes, but the magnitude of the GH spike is greater in boys.

There are changes in body proportions as well as composition during adolescence. The relationship between the shoulders and hips changes depending on sex. In boys the shoulders increase in comparison with the hips, whereas the hips widen relative to the shoulders in girls. Similarly, the relationship between leg and trunk lengths changes. In boys the lengthening of the femur is greater in proportion to overall bone growth than it is in girls. This leads to longer legs in boys. Growth of the bones of the face also affects appearance between childhood and adulthood. Mandibular length increases and the frontal sinuses evolve. This results in the protrusion of the jaw, a more upright alignment of the incisors, and creation of a brow ridge. The nose extends downward and forward to a greater extent as well (Wheeler 1991).

It is common for adolescents to worry about their health and whether they will be “normal” adults. The broad range of height and sexual maturity seen at any one time during adolescence can be a source of concern, particularly for those who are “late bloomers.” Both sexes worry about being too tall or short. A boy or girl whose “growth spurt” is very early or late can be reassured that this timing does not influence eventual height (Abbasi 1998, Gasser et al. 2001). Generally, pubertal growth accounts for 17 to 19% of adult height. It also appears that late-maturing individuals have longer legs than those who mature early, although significant overall height differences are not observed (Gasser et al. 2001). Genetic endowment (i.e., parental height) remains the greatest single determinant of height in well-nourished individuals and accounts for approximately 55% of the variance (Harrap et al. 2000). Moreover, there are indications that the genetic mechanisms underlying height are coming into focus. One contribution may relate to polymorphisms of CYP19,
which metabolizes aromatic substances such as androgen to estrogen. Since estrogen influences when the epiphyses close and the growth of long bones, the efficiency of androgen metabolism could play a role in determining height. Ellis and coworkers (2001) studied the interplay between the Y chromosome and CYP19 sites and reported that these sites have additive effects on height in males.

The physical changes of puberty and adolescence produce a wide variety of psychological effects. These changes affect the way others look at adolescents and how adolescents view themselves. The rate and timing of these physical changes have a powerful effect on later psychological, social, and emotional development. The individual may be thrust into roles or responsibilities prematurely or, conversely, may be denied access to privileges. The influence of hormones on the behavior of adolescents has also come to be questioned. “Raging” hormones continue to be advanced as an explanation for teenage behaviors. However, many studies show inconsistent or modest correlations between hormone levels and types of adolescent behavior (Hill 1993).

**Brain Development**

By the 1980s, it was known that brain myelination proceeds throughout childhood and adolescence accompanied by synaptic pruning, the reduction in exuberant synaptic connections seen in the neonatal period (Huttenlocher 1979, 1990). These findings emerged from anatomical studies of postmortem brains and were followed by PET studies in the 1990s (Chugani et al. 1987). However, the patterns and timing of these brain changes and implications for cognitive functioning are becoming clearer (Sowell et al. 2002). Casey and coworkers (1997) investigated increasing skills in attentional processes and related these to brain growth through adolescence using structural MRI. They suggested that the time table for various developmental changes might be different in different brain regions. In one study, they reported that the right anterior cingulate gyrus grew more than surrounding areas of the cerebrum and related to increasing attentional skills (Casey et al. 1997). Subsequent structural and functional MRI (fMRI) investigations have revealed a pattern of myelination and pruning that proceeds from posterior to anterior and inferior to superior regions (Sowell et al. 2002).

Between childhood and adolescence, whole brain volume increases about 9–12%, and this is noted to be roughly equal in the cerebrum and cerebellum (Giedd et al. 1999, Sowell 2002). Cerebral spinal fluid increases by nearly 100% during the period from late childhood through adolescence (Sowell et al. 2003). Overall, throughout childhood and adolescence these larger volumes appear to arise from increases in white matter. During childhood there is a general, modest increase in gray matter that reaches its peak in adolescence these larger volumes appear to arise from increases in white matter. Boys reached the maximum volume in the frontal lobes at 12.4 years and girls at 10.2 years. In the temporal lobes, the pattern was reversed—boys peaked at 16.2 years and girls at 16.7 years. More remains to be learned about the amount of these changes in different regions; there are some data to suggest that the greatest changes arise in frontal and parietal regions (Sowell et al. 1999, 2002). Sowell and coworkers (2003) reported on gray matter density changes from mid-childhood to adulthood. They observed a linear decline in parietal and frontal gray matter density from age 7 to 78 years. However, in the left posterior temporal region, subserving language functions, density continued to increase up to age 30 years before beginning to deteriorate (Sowell et al. 2003).

Development of some subcortical gray matter structures also appears to show sex-specific patterns of growth. The amygdala appears to increase during adolescence in males and is associated with a greater number of androgen receptors (Lenroot and Giedd 2006). Conversely, females display continued growth and enlargement of the hippocampus, a structure with a higher density of estrogen receptors (Lenroot and Giedd 2006). The data on sex differences in growth of white matter are inconsistent. One of the largest longitudinal studies has not observed sex differences in white matter development (Lenroot and Giedd 2006), but others have (De Bellis et al. 2001). There is general agreement that increasing size in white matter regions is seen throughout adolescence (Lenroot and Giedd 2006), and this is particularly true of the corpus callosum. In an extension of their studies of brain development, Sowell and coworkers (2007) replicated finding of greater brain mass in males than in females and that males had larger brains in every region. However, there were significant sex differences in the thickness of the cortex in specific regions. The greatest differences were observed in right inferior parietal and posterior temporal regions, where females exhibited nearly 0.5–0.6 mm greater cortical thickness (Sowell et al. 2007). These differences were apparent by early childhood and were also noted in adults (Sowell et al. 2007). The implication of these differences is less clear; greater thickness may reflect greater synaptic connectivity or decreased synaptic pruning (Sowell et al. 2007).

The mechanism by which sex differences affect gray matter growth is open to speculation. It may be that synaptogenesis and pruning are influenced by sex hormones (Giedd et al. 1999). De Bellis and coworkers (2001) point to work suggesting that estradiol increases synaptogenesis and decreases pruning, while testosterone may promote myelination.

These findings are exciting because they link the development during adolescence of specific cognitive skills such as organizing information, conceptualization, perspective taking, and social perception to structural changes in frontal cortical and subcortical structures (Sowell et al. 2001). With further study, we may illuminate the circuitry and brain regions subserving these functions and learn about how they are influenced by experience, hormonal events, and genetic expression.

**Cognitive Development**

The child’s cognitive apparatus undergoes dramatic transformations throughout adolescence. This maturation of the child’s capacity for thinking and memory is as significant
as the physical changes that unfold throughout this time. The transformation itself is mediated by the emergence of novel cognitive skills that allow the manipulation of ideas and permit the adolescent to assimilate more highly complex information. The adolescent’s informational catalog expands, allowing the verification of new facts. Among the most important developments is the emergence of the ability to reflect on cognition itself; this is referred to as the development of metacognitive capacity, facilitating both understanding and empathy (Flavell 1981).

Piaget’s theories (Gelman and Baillargeon 1983) provide a fundamental starting point for understanding childhood cognitive development (Flavell et al. 1993) despite problems in the staging of skills at certain developmental times. Most of Piaget’s descriptions and sequences of skills have proved to be valid, but consensus is lacking on whether the skills aggregate or can be demarcated in a manner that supports Piagetian developmental stages (Flavell et al. 1993).

A major contribution of Piaget was the description of the ways in which the child’s conscious mind is transformed and recasts itself from an efficient but heavily subjective and relatively concrete memory and organizational tool into an exquisite “conceptual processor” during preadolescence and adolescence. But contemporary theory has suggested that there are limitations that must be acknowledged when trying to generalize from the capacities of preoperational and operational stages. It may be that there are some skills that come “online” at one phase of development but do not readily generalize to other functions as Piaget suggested. Logical skills in particular may display the least generalization. “Conditional reasoning begins to appear in elementary school years or earlier, but remains incomplete and imperfectly used even in adulthood. Truly abstract thought is a rarity and, if it appears in the adult at all, seems to be dependent on specialized training” (Mandler 1983).

In comparison with its developmental forerunners, the processing skill of the adolescent is capable of much higher levels of abstracting and conceptualizing. This higher-level processing capacity is linked closely to abilities to grasp novel attributes and perceive critical elements. As a result, concepts can now be manipulated as things in free-standing objects that may be uncoupled from actual experience. With this ability, critical elements can be applied across situations or subtracted out of a logical string of assumptions. Similarly, novel attributes can be generalized to other problems. Consequently, the adolescent begins to understand and apply concepts in imaginative ways outside the circumstances in which they were first learned or even without having observed them firsthand. When actions are under consideration, the more powerful processing skill permits the adolescent to imagine the outcome of a theoretical or conceptualized intervention without actually having experienced the situation or needing to perform the action directly. The adolescent acquires far greater capacities for comparing outcomes and imagining emotional consequences and, as a result, acquires far greater abilities to understand, integrate, and relate experiences and ideas.

For Piaget and Inhelder (1969), logical reasoning is “a transformation of thought that permits the handling of hypotheses and reasoning with regard to propositions removed from concrete and present observation.” It is this ability that undergoes rapid growth just before and during adolescence. These mechanisms equip the child with additional cognitive abilities such as a combinatorial system, an ability to understand combinations of objects, an acquisition of new propositional combinations, and an appreciation of reversibilities like inversion, reciprocity, and symmetry (Inhelder and Piaget 1958).

Consequently, adolescents are able to understand, organize, and relate information in new ways. As Flavell and coworkers (1993) have described, adolescents are able to entertain ideas about possible alternatives that are not immediately in front of them. Adolescents readily grasp possibilities that are beyond the realm of reality or that may contradict all previous assumptions they have held. In addition, novel problem-solving methods become available. Deductions can be made from hypotheses that are no longer fashioned exclusively from facts that are known or apparent. Adolescents can conceive of outcomes from mental experiments that are based on concepts alone. Abstract ideas can be entertained. The consequences of living under the simultaneous coexistence of two competing value systems, neither one of which the adolescent has ever known, can be imagined and explored. Such skills extend beyond an ability to imagine or the creativity of manipulating these ideas; they are based on an ability to think beyond one’s self and one’s subjective experience.

Adolescents can understand the relationships between objects outside subjective experience. Adolescents learn to work from “intrapropositional versus interpropositional knowledge” (Inhelder and Piaget 1958). “Formal operational thinkers understand that logical arguments have a disembodied and passionless life of their own, at least in principle. Concrete–operational thinkers have enough trouble seeing what logically follows from credible premises, let alone from premises that actually contradict one’s knowledge, beliefs, or values” (Flavell et al. 1993).

These ideas formed the foundations of cognitive sciences for adolescence throughout the 1960s and 1970s. But during the past decade, there has been an elaboration and expansion of Piaget’s concepts, and they have been interwoven with discoveries from other lines of inquiry. Information-processing theory and the concept of metacognition have been major contributions to these modifications of traditional Piagetian views.

Information-processing theory posits alternative explanations for several of the most basic tenets that underlie Piaget’s constructs of cognitive development at this stage. A key acquisition of the adolescent in Piaget’s schema of this period is the ability to understand abstract theoretical concepts. He proposed that greater logical skills were at the core of this competence (Piaget and Inhelder 1969). However, an inviting alternative hypothesis from information theory suggests that the success of the adolescent, compared with the child in this arena, has less to do with logic than with experience and knowledge. Information theory suggests that the amount of knowledge possessed by the individual influences both learning efficiency and techniques. The developmental difference between children and adolescents stems from the latter’s “ability to access and flexibly use competencies they are known to possess. Development consists in part of going from the context-dependent state where resources are welded to the original learning situation to a relatively context-independent state where the learner extends the ways in which
initially highly constrained knowledge and procedures are used” (Brown et al. 1983). The hypothesis draws from observations of problem-solving techniques used by children and adolescents. In a series of studies, younger children appeared to reason through new problems one at a time. On the other hand, the more experienced adolescents or adults were able to (1) more readily distill the critical features of the new problem and (2) recognize how the new problem resembled other more familiar problems (Lovett and Flavell 1990).

Three mechanisms by which this efficiency occurs have been suggested: (1) more thorough processing of information, (2) greater capacity to transfer different learning strategies from one kind of problem solving to new problems, and (3) greater familiarity with the problems and solutions (Sternberg and Powell 1983). The higher success of the more experienced individual when presented with a novel problem does not appear to be attributable to more refined logic skills. One line of development through childhood to adulthood involves improvement in the completeness with which data are scanned and processed with increasing age (Sternberg and Powell 1983). Children tend to overlook or prematurely cease scanning information compared with adolescents.

A second factor influencing efficiency may be that more experienced solvers possess a better ability to withstand the confusion of new vocabulary, unfamiliar subjects, or new ideas (Chi et al. 1981) and to place the problem in the context of what they know. This ability to place the problem in the context of other knowledge is called transfer processing (Sternberg and Powell 1983). “Transfer components are processes involved in carrying over retained information from one situational context to another” (Sternberg and Powell 1983). One factor promoting facility with transfer skills is experience. “Novices tend to use key words in the problem format when they are asked to sort problems into types; in contrast, experts generally sort on the basis of underlying conceptual identities” (Brown et al. 1983). Information theory suggests that when the common elements of a problem can be discerned, the access to knowledge about this type of problem is greater and an approach to its solution is more likely to be found.

Familiarity with the type of problem is another important advantage of experience (Glaser and Chi 1988). With greater experience and knowledge, an individual is more likely to recognize a familiar pattern—a so-called problem isomorph—within the new problem (Brown 1982). Experience increases the individual’s ability to recognize the pattern and to transfer knowledge of the solution from a similar problem to the new one. The techniques of problem solving also change as a result of this knowledge. Instead of working through to find the solution each time, the more experienced individual relies on familiar strategies, rote learning, and analogy. If the isomorph is discerned, the method is applied and the solution can be recalled; the answer to the new problem follows by analogy.

Metacognition, as used by Brown and Flavell and their coworkers, refers to “any knowledge or cognitive activity that takes as its objects, or regulates, any aspect of any cognitive enterprise.” In other theories, metacognition is encompassed in the wider category of executive control or processes (Flavell et al. 1993, Brown et al. 1983, Sternberg and Powell 1983). The ability to think about thinking means that the adolescent can consider her or his own thinking styles, aptitudes, and limitations. Moreover, this reflective capacity can be applied to understanding others. A deeper appreciation of the way others think and how their thinking influences their behavior reaches the grasp of the adolescent.

A typical school-age child who is asked to reason out the behaviors involved in an interpersonal exchange between two others is inclined to draw on only the interactions that were perceivable at the time—in the here and now. Such a child has only a rudimentary capacity to understand what prior experiences may have contributed to the thoughts or feelings that influenced the exchange.

Unlike the younger child, the adolescent with metacognitive skills understands something about the act of thinking and the antecedents of feelings. The adolescent thinks about the perceivable elements of the exchange—the overt proximal emotional and environmental factors—but also understands that thought and perception may be influenced by a host of internal events that lie beyond what is visible. The modal adolescent is aware of a wider array of internal states, subjective motives, and unique historical forces; adolescents know that each person possesses an inner life and a past that impinge on current behavior and thought. Thus, the adolescent is aware that people have unique histories that affect their assumptions and perceptions and influence their thinking and actions. Adolescents also know that thinking itself can be influenced by fatigue or emotion. This permits typical adolescents to compare their observations with knowledge of behaviors or influences that are foreign to their subjective experience.

Some elements of metacognition begin to appear in childhood and are relatively well established in the later part of childhood. One component of metacognition that emerges in childhood but is extended considerably throughout adolescence is cognitive monitoring (Flavell 1981). In one study, two groups of children, one of school-age children and another of preschoolers, were asked to memorize a small series of simple items and decide for themselves when they were ready to recall them from memory (Flavell et al. 1970). The younger children were significantly less prepared despite their claims of readiness; the older children were considerably more competent. Tasks such as this hinge on an ability to understand one’s own thinking or gauge one’s own learning ability. In adolescence, the ability to reflect on thinking moves to a higher level. This next level, which relies on the so-called recursive reasoning, permits one to reflect on another’s thinking about oneself. The capacity to “think about your thoughts about my thoughts and so on” (Flavell 1988) is an important cognitive and developmental milestone. On reaching it, the adolescent acquires a greater understanding of thought and behavior.

The applications of recursive thinking have educational and interpersonal relevance. In literature, they permit the more developed adolescent to imagine what the protagonist would think about how the antagonist would regard the protagonist’s thoughts. This sort of “mind game” is the basis for a variety of theatrical intrigues. For example, character A attempts to outthink or “psych out” character B by anticipating what B would predict of A’s line of reasoning. A may even attempt to lead B in a certain direction, anticipating that this would encourage B’s presumption. A then exploits B’s predictability. A acts in a different way than B has assumed in order to gain the advantage of surprise.
It is no coincidence that this ability to conceive of ways in which peers, parents, and authority figures think about how one is thinking is associated with a time of immense social self-consciousness and preoccupation for the adolescent. In interpersonal endeavors, recursive thinking permits adolescents to imagine misunderstandings and distortions that may arise between themselves and their friends and thus respond in ways that repair mistakes. They can imagine the reactions that would follow from what others think about them. Conversely, these abilities can be used to tease or manipulate others at a more sophisticated level of destructiveness. These skills may also be applied to test taking and essay assignments, in which the student thinks about the instructor’s thoughts about her or his likely responses to the question.

In summary, a number of salient features distinguish the cognitive development of adolescents. The capacity to grasp conceptual underpinnings and to manipulate them as objects themselves appears consistently across nearly all theories of cognitive development and might be regarded the most significant. Information theory departs from the traditional Piagetian reliance on development in logic skills during this phase. It asserts that larger foundations of information and better skills in discerning the isomorphic features shared by new and familiar problems are critical. In addition, more thorough scanning skills, flexible use of learning strategies, and control or monitoring of information processing appear to be important (Sternberg and Powell 1983). Development of metacognitive skills has emerged as a vital developmental activity during adolescence, based on studies of knowledge transfer and executive function processes (Flavell et al. 1993).

Executive functions are a hypothetical set of cognitive skills that guide goal-directed activity (Anderson 2001, Shallice and Burgess 1991). They often refer to inhibition of prepotent responses, working memory, attention, goal setting, mental flexibility, and organization. There is evidence that many of these executive functions rapidly develop during childhood and remain relatively stable or increase during adolescence (Anderson 2001, Adleman et al. 2002). Two exceptions are sharp increases in attentional control and processing speed seen in midadolescence (Anderson et al. 2001) and smaller but significant increases in goal-setting skills in early adolescence (Anderson et al. 2001). Active investigations now focus on the links between enhanced executive skills and fMRI findings of increasing frontal lobe myelination during adolescence. The increasing volume of the anterior cingulate and dorsolateral prefrontal cortex during adolescence are particularly remarkable, as these regions are thought to play an important role in attention and inhibitory functions (Casey et al. 2000). Similarly, in a study from childhood through adulthood of the Stroop task, which is linked to cognitive interference skills, Adleman and coworkers (2002) noted increases in activation in left lateral prefrontal and left anterior cingulate activity with age and skill performance.

A growing body of literature suggests that changes in brain function from infancy to adulthood may be about specific regions but also about interactions between regions (Johnson 2001, 2003). Johnson (2001) has described the older, maturational view as considering functions based on the development of specific brain regions. Increasingly this idea has been augmented by encompassing neural circuitry—the relationship and organization of circuits between regions. Two subtypes of interaction emerge from this view. In one, the reinforcement of interactions between regions increases the efficiency, organization, and number of connections between them (Johnson 2001). In the other, the skill-learning view (Johnson 2001, 2003), a specific brain regions might be recruited for learning a function. As the skill becomes honed and routine, its location and activation shift so that it eventually resides elsewhere (Johnson 2001).

A time line of cognitive development from age 13 to 18 years is presented in Figure 11–8.

### Cognitive development

**Formal operations:** Development of logical reasoning, including combinatorial system, ability to understand combinations of objects and new propositional combinations, appreciation of inversion, reciprocity, and symmetry.

**Resolution of adolescence:** Attain a personal value system respecting the needs of others and the needs of self.

**Figure 11–8 Cognitive development during the adolescent period (age 13–18 years).**
Emotional Development

During adolescence, emotional development is advanced and shaped by experience and cognitive maturation. The emotional life of children in middle childhood can be characterized as relatively concrete, instantaneous, and circumstantial. They have access to a wide array of emotions, can distinguish subtle gradients of difference, and can identify these emotions in others as readily as in themselves. They worry about how others think of them and display empathy for their friends. However, a deeper appreciation of others’ sentiments is limited by the school-age child’s ability to understand the mental lives and motives of others who have a different sense of time, experience, and memory. In contrast, adolescents are capable of perceiving a range of events from an individual’s distant history that may be influential at the present time. They can reason that events well outside their shared experience with an individual might be strongly influential, and they can reason backward from the sequence of events and emotions to speculate on motives or feelings that might be at work. Capacities for abstraction permit adolescents to consider factors outside their own immediate emotional experience. Consequently, adolescents are more emotionally interactive than at any previous period of development.

Emotions can be more thoroughly understood and explored within the context of the various cognitive changes that occur during adolescence. Emotions in adolescence exert an increasingly important role in guiding behavior. They become a sustaining motivation for behaviors and mediate the adolescent’s relationship with peers and family. There are differences of opinion about whether adolescents are actually more emotional than school-age children. Psychoanalytic theory proposes that emotionality arises as a consequence of efforts by the ego to integrate conflicts between wishes or drives and social demands. The theory suggests that these developmental conflicts achieve a comfortable equilibrium during the latency years before puberty and are remnants of what was incompletely resolved in toddlerhood. The intrusion of the biological drives of adolescence is believed to upset this equilibrium and force the conflict to resurface in a new way and at a different level. Just as in toddlerhood, the child is confronted with internal pressures that must be brought into alignment with social and familial demands. The social demands on adolescents have different objects and aims, but the task of accommodation remains much the same. Similarly, the outlets available for managing the conflict in adolescence are more diverse and are influenced by more mature cognitive and physical capacities.

Psychoanalytic theory proposes that this conflict is not only typical of adolescence but is inevitable in the developmental process. Consequently, a lack of overt conflict should be viewed as atypical. “Convenient as this may be, it signifies a delay of normal development and, as such, is a sign to be taken seriously. These are children who have built up excessive defenses against their drive activities and are now crippled by the results which act as barriers against the normal maturation processes of phase development” (Freud 1958).

Empirical investigations do not support this hypothesized increase in emotionality (Larson and Lampman-Petraitis 1989). Direct sampling of adolescents revealed no greater quantity of emotional feeling than is found among children in the preteenage period. In addition, research on nonclinical populations does not support the concept of a disruption of the equilibrium from middle childhood. Investigation suggests that emotional tone remains quite stable from middle childhood through adolescence. Moreover, the stability of these measures was observed across several different cultures (Offer et al. 1981). Overall, the empirical investigations offer little support for the idea that adolescence is a period of emotional turmoil, just as there is minimal support for the concept of a normative period of intense conflict between parents and adolescents.

One way to reconcile the difference between the clinical observations and the research findings is to observe the quantitative increase in emotional disorders arising during this time. A variety of studies support the premise that anxiety and depression rise steeply, particularly among girls, during adolescence (Buhrmester 1990). Clinicians are in the position of treating adolescents with these disorders and are thus at risk of erroneously generalizing their experience to the entire population. “Office epidemiology” may be quite an accurate reflection of incidence trends of psychopathology but is inappropriate when generalized or applied as prevalence in the nonclinical population.

Another way to reconcile these different perspectives draws on studies of the means by which adolescents resolve conflict compared with the methods used by younger children. The cognitive set of adolescents promotes seeking advice and looking to peers for sympathy. There are cultural and sexual differences in the quantities of and conventions surrounding these exchanges (Seligge-Krenke 1990). However, whatever culture is being considered, there are differences in the amounts of discussion and intimate exchange that occur in adolescence, compared with earlier periods of development (Buhrmester 1990). Thus, emotional expression and discussion about conflict may increase in adolescence and lead to the distorted perception that the actual amount of turmoil has increased. This is analogous to the incorrect presumption of increasing crime rates that follows the expanded availability of police. The ease of reporting decreases barriers to detection and rates appear to rise. Thus, although the emotional life of adolescents is more complex and more interpersonal than that of younger children, it does not appear that the developmental changes of adolescence are in themselves sources of increased emotionality.

A time line of emotional development from age 13 to 18 years is presented in Figure 11–9.

Social Development

Unlike the relatively clear biological criteria defining puberty, the demarcation of adolescence is variable because it is basically designated by society; that is, society determines the criteria for adolescence. At times there are social pressures that dictate whether a larger or a smaller proportion of the teenage population are considered to be adults. For example, when the economy is depressed, teenagers competing with adults for jobs are an economic threat. Conversely, when there is a war, the demand for military personnel defines that it is appropriate for strong and vigorous teenagers to become soldiers. Enright and colleagues (1987), taking a developmentalist’s perspective, studied this bias by tracing articles published in the Journal of Genetic Psychology from 1890 through 1945. This span encompassed two periods of
depression and both world wars. The research focused specifically on the attributes assigned to teenagers during these four periods. Through the two depressions, youth tended to be described as relatively childlike and immature, obviously still needing time before becoming adults. During the two wars, youth were more often described as mature and developmentally ready to fight for their country.

Two examples illustrate how the perception of the maturity of teenagers changed in the twentieth century. The first was in response to the Great Depression, when, in 1938, the Congress passed the first federal child labor laws to protect adults, many of whom had families to support. The second was during the Vietnam War. The age of legal maturity at that time was defined as 21 years, but soldiers were drafted at age 18 years. The media made much of the fact that the government forced 18-year-olds to fight (and die) for 3 years before they were allowed to buy alcohol legally or vote. In response, the Congress lowered the age of majority to 18 years. The media made much of the fact that the government forced 18-year-olds to fight (and die) for 3 years before they were allowed to buy alcohol legally or vote. In response, the Congress lowered the age of majority to 18 years. Since then, there has been mounting concern about teenagers’ deaths caused by drunken driving. Therefore, although the voting age and age of entry into military service have remained at 18 years, states have raised the legal age for drinking alcohol to 21. The latter was strongly encouraged when federal dollars for state highway projects became dependent on the state’s drinking age being 21. Highway funds will also be cut for states that by 2004 do not use 0.08 as the blood alcohol standard for drunk driving. A new approach by states that is gaining popularity is the “graduated” driver license based on set periods of time and the absence of violations. For example, the youth first obtains a license that requires the presence of a licensed adult. With a level-two license, the young person can drive alone from 5 AM to 9 PM, and, thereafter, a full license is granted. Some data show that this approach can cut down the number of youth crashes (Foss et al. 2001).

Just as state and national policies affect a teenager who is considered to have reached adulthood, so do more local and personal pressures such as family and ethnic expectations. These may favor a teenager’s being regarded as an adult earlier or later than another youth of the same age. Poverty is an important factor that influences crucial aspects of life such as nutrition, health care, housing, recreation, and education. Other factors such as race or ethnicity can also affect many facets of life. For example, minority adolescents are much more likely to be raised by a single parent. This in turn is associated with a higher likelihood of poverty, less education, increased drug use, and, for a woman, raising a child as a single parent. Similarly, African-American and Hispanic youth have been shown to be at greater risks of certain injuries and illnesses. Although homicide rates have fallen since the early 1990s, the greatest risk for African-American adolescents, particularly male adolescents, is that of being murdered. The homicide rate for 15–20-year-old black males is more than six times that for white males and twice the rate for Hispanic males (Centers for Disease Control and Prevention 2001). According to the National Commission on Children, “teenage boys of all races are more likely to die from gunshot wounds than from all natural causes combined” (National Center for Health Statistics 1988).

Suicide rates are higher for white than for African-American teenagers (Centers for Disease Control and Prevention 2001). This ratio, however, has remained relatively stable, compared with the widening racial gap for homicides. As with homicides, firearms have become increasingly popular for committing suicide.

![Emotional development](image-url)
Age at onset and type of sexual experiences are associated with social and ethnic background. The family is the first and foremost conveyor of culture. A child’s expectations for sexual activity stem mostly from parent or parents, relatives, and neighbors. African-American adolescents of both sexes are more likely than their Hispanic or other white peers to have had sexual intercourse at each age through the teens (Mott and Haurin 1988). Although education and economic variables are influential in the timing of first sexual experiences, timing is also powerfully molded by what is considered normative (Furstenberg et al. 1987). Early sexual activity in turn is linked to early pregnancy and to a greater likelihood of contracting sexually transmitted diseases. Condom and other contraceptive use is more common as adolescents become older. Self-esteem and sexual activity are linked to the adolescents’ personal beliefs (Miller et al. 1987). If the teenager believes that sexual experience is a positive activity, abstinence lowers self-esteem and participation raises it. The teenager develops a mental value about sexual activity through his or her experiences during the first 12 years of life.

Early sexual experience is not only a social issue, but also a serious health risk. All sexually transmitted diseases are more common among poor and minority teenagers than in any other groups. There has been an increase in sexually transmitted diseases in adolescents. A national risk surveillance survey of high school students in 1999 gave an update of the behavior patterns and how they did or did not vary from a similar survey in 1991 (Centers for Disease Control and Prevention 2000). Significant ($p < 0.05$) increases were found in the use of marijuana and cocaine. By the same token, condom use was up, along with seat belt and bicycle helmet use. Physical fighting, carrying a gun or other weapon, and sexual promiscuity were all significantly down. Human immunodeficiency virus (HIV), other sexually transmitted diseases, and unwanted pregnancies correlated with age at time of first sexual intercourse and frequency of intercourse. Half of the high school students had intercourse. The racial percentages for black, Hispanic, and white students were 71.2%, 54.1%, and 45.1% respectively.

Although the acquired immunodeficiency syndrome (AIDS) is seldom diagnosed during the teenage years, it is often at this time that HIV infection is contracted. AIDS does not occur until 7, 10, or more years after infection. In a study of African-American young people, aged 9–15 years, rates of foreplay even among the 35% who were sexually active were quite low, but among those who were sexually active, 24% of boys and 35% of girls had anal intercourse, a strong risk factor for HIV infection (Stanton et al. 1994). Only about 60% of these youngsters reported that they used a condom during their last intercourse. In 1989, 92% of births to African-American adolescent mothers occurred outside marriage. Pregnant adolescents are more likely than other mothers to deliver low-birth-weight infants, who in turn are more likely than average-sized infants to have developmental delays.

Early sexual activity, alcohol and other drug use, early pregnancy, and sexually transmitted diseases are all intercorrelated (Elster and Kuznets 1994). They all embody risk taking and increase the likelihood of injury, disease, and further poverty. An estimated 25% of 10–17-year-olds engage in behaviors that create a serious danger to themselves or others (Dryfoos 1990). Drug and alcohol use correlates with decreased use of condoms. Drug use may reduce sexual inhibitions, and sexual favors may be sought in exchange for drugs or money for drugs. Transmission of HIV arises from unprotected sexual intercourse or the injection of drugs.

Parents often feel unappreciated by teenagers or envious of the increasing beauty, strength, or intelligence of their offspring. Giving up control over their children may also represent to parents that they are aging and less needed. The ability to exchange points of view can moderate this conflict. Extremes can be destructive; too few parental rules can be just as much a problem as too many. When parents are absent psychologically, teenagers may increase their misbehavior to learn what limits exist. If there are no parental limits, social limits become salient.

Brion-Meisels and Selman (1984) have described an invariant sequence of five stages of moral perspectives. Selman’s third stage usually comes just before or during preadolescence and permits the child to put her or his viewpoint aside and take the perspective of another person. The fourth stage occurs in the early teens and includes mutual perspective taking, the ability to take the perspective of a neutral third-party observer. Obviously, the ability to accomplish these stages is related to intelligence and the quality of social morality displayed by parents and mentors to the adolescent throughout childhood. This sequence of moral stages cannot be accelerated, but it can be slowed or stopped.

Conflicts between teenagers and their parents typically intensify about the time of puberty and begin to subside after secondary sexual characteristics become evident (Hill 1993). Most parent–child quarrels begin over minor issues and do not escalate. Baumrind (1971) has classified parental discipline into authoritarian, authoritative, and permissive types. Permissiveness is characterized by too few rules, whereas authoritarian parenting is quite strict and does not balance punishment with praise for positive behaviors. The authoritative approach includes consistency, firmness, and a warmth for the adolescent as well as reinforcement of his or her mature responses (Baumrind 1971). Authoritative parenting appears to be associated with the acquisition of positive social attributes (Hill 1987). It is also remarkable that the overall incidence of family abuse and neglect is, if anything, higher for adolescents than it is for younger children (Council on Scientific Affairs 1993).

Peers become more influential as a child enters adolescence, and peer pressure can be socially positive or negative. Children seem most susceptible to peer pressure in early adolescence, and this begins to lessen after age 13 or 14 years (Hill 1993). Most early teenagers believe that their parents are not objective enough to help them resolve doubts about parental values and viewpoints. To a large extent, during early adolescence, the peer group comes to represent the stamp of normality and an assurance of acceptance. Typically, adolescents who have many friends possess high self-esteem. Friends may change their individual behaviors to conform to the group, or groups may be formed because of shared peer interests. Both processes probably occur (Kandel 1978). Teenagers often quit groups that are not sufficiently homogeneous or have unacceptable expectations.

It is common for parental abuse or neglect to push adolescents into associations with adverse peer influences. Boys seem more influenced by group pressures toward antisocial
behavior, but otherwise the relationships between gender and group conformity do not show consistent findings. Under peer pressure, cigarette and alcohol use may rise (Fisher and Bauman 1988), but so may school grades (Epstein 1983). Not all groups or group members are equal. Some group members are more influential than others, and some groups are more demanding of members. Peer groups in early adolescence tend to be rather narrow, same-gender cliques, but they become mixed gender, larger, and more loosely structured by later adolescence. Adolescents who cannot make friends usually manifest emotional, social, and academic problems. Their self-esteem tends to be low. Peer acceptance and support are less available to these individuals (East et al. 1987).

Schools are where adolescents typically spend most of the time that they are not at home. Doing poorly in school and dropping out of school are highly correlated with having behavioral, social, and legal problems (Rutter 1983). According to the Educational Testing Service, which is responsible for testing aptitude for admission to college, fewer than half of American 17-year-olds have the skills and basic knowledge required for college or for many entry-level jobs (Applebee et al. 1989). About one in eight adolescents drops out of school. Four of five prison inmates are high school dropouts (Committee for Economic Development 1991), who are nearly twice as likely as high school graduates to be unemployed (US Congress, Office of Technology Assessment 1990). For adolescents from families and neighborhoods that have powerful antisocial tendencies, school offers one possible way to learn other values and other paths to being successful. Friendships, skills, and mentoring are all positive attributes that can be obtained through school.

The decision to drop out of high school carries with it potential risks that are seldom foreseen by the teenagers themselves. Part-time work during high school may be positive or negative, depending on the experiences provided and whether or not educational and social opportunities are critically curtailed. Part-time work for more than 15–20 hours per week usually undermines basic education (William 1988).

The standardized age of 21 years for legal drinking did in the 1990s correlate with a number of positive public health statistics. A later age for the onset of drinking is associated not only with less fighting throughout a male’s life (Hingson et al. 2001), but also with fewer pregnancies and sexually transmitted diseases.

A paradox of independence is produced for youth who attend college, live away from home, and have their parents help pay for it all. The young person living away from home is legally an adult but remains financially unemancipated. Graduate or professional school further prolongs the interval between adolescence and adulthood. Some young people cannot tolerate this protracted period of dependency and either quit school or stop taking money to achieve financial liberation from their parents.

A time line of social development from age 13 to 18 years is presented in Figure 11–10.

**Risk Factors, Protective Factors, and Gene–Environment Interactions**

The epidemiology of serious psychiatric disorders points to adolescence as a time of increased risk. It has
been established that incidence rates for depression (Angold 1988, Joyce et al. 1990), bipolar affective disorder (Akiskal et al. 1985), panic disorder (von Korff et al. 1985), substance abuse (Compton et al. 2007), anorexia nervosa (Lucas et al. 1991), bulimia nervosa (Kendler et al. 1991), substance abuse (Compton et al. 2007), antisocial behavior (Rutter and Giller 1983), and schizophrenia (Angermeyer and Kuhn 1988) either peak or display a major increase during adolescence. Why adolescence should be the developmental period of greatest risk for so many chronic psychiatric disorders remains unclear. At one point it was thought that the total number of stressors or the quantity of adversity might account for the appearance of disorders. Sameroff (1989) noted, “except at the extremes of biological deviation, it is the number rather than the nature of risk factors that is the best determinant of outcome.” Examples of individual biological vulnerabilities were male sex, low birth weight, mental retardation, and prenatal exposure to large amounts of alcohol. However, a modern view points to the specific interplay of biological, familial, social, and cultural forces in the emergence of serious disorders. Only recently have we begun to appreciate the mechanisms behind some of these interactions. Studies in the last decade showing specific gene–environment interactions have transformed our understanding of risk and protective factors across development and opened a rich avenue for further investigation (Moffitt et al. 2005). These efforts have substantially affected our understanding of the mechanisms by which one’s genes and environment shape development and lead to disorders. Rutter and coworkers (2006) trace the history of thinking about this interplay of genes, environment, and psychopathology. Rutter and coworkers (2006) emphasize how our view of genes as solely and inevitably determining an outcome has modified to one of genes as relative risk factors. In this sense, susceptibility genes are “part of multifactorial causation and not any direct genetic effect....In most cases, the susceptibilities are dimensional, rather than categorical” (Rutter et al. 2006). The expression of a genetic sequence is profoundly affected by accessory chemical reactions that may in turn be switched on by events. Several premier examples have surfaced showing that these epigenetic factors—environmental influences on gene expression—play a fundamental role in the development of psychopathology.

Examples of gene–environment interaction are the effect of early maltreatment in combination with polymorphisms of the promoter region coding for monoamine oxidase A (MAO-A) leading to antisocial behavior and violence (Caspi et al. 2002, Kim-Cohen et al. 2006) and the effect of life stress in combination with functional polymorphisms in the promoter region of the serotonin transporter gene on the onset of depression (Caspi et al. 2003, Eley et al. 2004).

MAO-A, an enzyme coded by a gene on the X chromosome, metabolizes catecholamines including norepinephrine (NE), dopamine (DA), and serotonin (5-HT) in brain. Caspi and coworkers (2002) were aware of findings from animal and human research that weak MAO-A is associated with aggression and that maltreatment in childhood may lead to antisocial behavior and to persistent elevations of 5-HT, DA, and NE. They sought to learn how MAO-A deficiency and early maltreatment might be linked. To do this, the investigators genotyped 1037 boys who had been characterized and followed for more than 23 years as part of an epidemiological sample in a longitudinal study of child growth and development. A strength of choosing an epidemiological sample is that there were a range of early-life experiences among the boys—8% were identified as having experienced “severe” maltreatment, 28% “probable” maltreatment, and 64% no maltreatment. The investigators grouped the sample according to high and low MAO-A activity (63% and 37% of the cohort, respectively). Only boys were chosen because their single copy of the X chromosome allows for a simpler, dichotomous classification of MAO-A activity (high or low). Females possess two copies of the gene and MAO-A activity may be low, medium, or high. The sample of boys was reviewed for presence of DSM-IV diagnoses of conduct disorder, antisocial symptoms, and criminal convictions for violent crimes. Among adolescent boys who suffered probable or severe maltreatment and had low MAO-A activity, presence of a DSM-IV diagnosis of conduct disorder was nearly three times more likely than among those with no maltreatment (the odds ratio (OR) was 2.8, 95% confidence interval (CI): 1.42–5.74). However, among boys with high MAO-A, the effect of maltreatment was much smaller and failed to reach significance. (OR 1.54, 95% CI: 0.89–2.68). ORs for measures of antisocial behavior, conviction for violent offenses, and self-reports of violent behavior produced similar results. Thus, having both early maltreatment and low MAO-A substantially increased the risk of conduct disorder and violence later in life. In contrast, having either high MAO-A or an early life free of maltreatment conferred some measure of protection against the emergence of these antisocial behaviors.

Caspi and coworkers (2003) also examined the relationship between stressful life events and polymorphisms of the serotonin transporter (HTT) gene. The role of serotonin in depression is suggested by findings of abnormalities in serotonin physiology and the effectiveness of medications targeting serotonin dynamics. The serotonin transporter is the major mechanism for clearing serotonin from the synaptic cleft and is also the site of activity for selective serotonin reuptake inhibitor (SSRI) medications. The transcription of proteins for HTT is under the control of a gene, termed the HTT-linked polymorphic region (HTTLP R), on chromosome 17 (17.11.1-q12), and the efficacy of SSRIs has been linked to alleles of this controller gene (Serretti et al. 2007). There are several alleles of the HTTLP R region, including at least a long “I” version that is efficient and short “s” allele that is inefficient in transcribing the HTT protein. The investigators were aware of the extensive work suggesting a relationship between depression and low activity of HTT. As before, Caspi and coworkers (2003) drew from the Dunedin Longitudinal study and ascertained 847 Caucasian, 26-year-old individuals, of whom 17% were homozygous for the “s” allele, 51% were heterozygous, and 31% were homozygous for the “I” version, distributed similarly in both sexes. The participants were then asked to rate presence of stressful life events since age 21 years and individuals were grouped according to the number of adverse events. The cohort was then assessed for the presence of DSM-IV major depression in the past year, and 17% met criteria for depression, 58% of whom were female. When analyses of the effect of recent stressful life events were performed excluding those with a history of depression prior to age 21 years, being “s/s” or “s/l” significantly predicted major depression and
did not predict depression in “l/l” individuals. Among those who reported suffering four or more stressful life events, 10% had at least one copy of the “s” allele yet they accounted for 25% of all the cases of depression, and one-third of those with an “s” allele became depressed—nearly twice the rate of those who were “l/l” (Caspi et al. 2003).

These methods reveal why lower levels of analysis failed to find effects. Looking at disorders using only genetic data, or using only data on earlier environmental exposure, or only the developmental period when the disorder had it onset would never illuminate these mechanisms. Gene–environment interactions require the integration of our knowledge of gene action, the neurophysiology of disorders, genetic influences on the receptors and substrates behind that physiology, and how epigenetic events can influence genetic expression.

A great deal remains to be learned about the nature of environmental stressors and how they affect the individual. The potency of any particular stressor appears to vary with age and sex. Boys appear more vulnerable to both physical and psychosocial stressors from the prenatal period to about age 10 years; girls grow more vulnerable to stressors during their teens (Mrazek and Haggerty 1994). Similarly, maternal inattention during childhood plus residence in high-crime neighborhoods in adolescence appear to associate with substance abuse in adolescence (Cohen et al. 1990).

Temperamental factors are also relevant. The combination of difficult temperament and parental psychopathology appears to produce a particularly malignant prognosis (Rutter and Quinton 1984). A variety of parental and familial attributes have been proposed to influence the onset of child and adolescent psychiatric illness. Examples that have been advanced include high levels of parental personality disorder and depression, expressed emotion, unavailability of mother, marital discord, and low degree of family cohesion. Hill (1993) suggested that “early puberty, authoritarian or permissive parenting, family disruption, large impersonal schools, and the availability of a negative peer culture” are important. In addition, Hill (1993) notes “a low level of parental monitoring of the adolescent’s behavior [is] a risk factor for involvement with antisocial peers” (also Patterson 1986, Patterson and Stouthamer-Loeb er 1984). Similarly, temperamental factors can moderate the course of illness (Zanarini et al. 2006).

*Goodness of fit* is another concept from temperament research that is relevant for adolescent development and risk. Chess and Thomas (1984) defined goodness of fit as that which “results when the environmental expectations, demands, and opportunities are consonant with the individual’s temperament and other characteristics so that he can master them effectively.” Conversely, *poorness of fit* occurs “when the environmental demands are excessive for the individual’s capacities, so that excessive stress and an unhealthy developmental course may be the result” (Chess and Thomas 1984). In this paradigm, stress accompanies developmental progress even when the fit between parent and child is good. The difference between good fit and poor fit is the degree to which parents provide support, modulation, and buffering so that stress and demands are no greater than the child’s capacities to assimilate them (Chess and Thomas 1984). When adolescents possess biological vulnerabilities and there is a poor fit between them and their parents, the risks of a poor adaptation and maximal expression of the vulnerability are increased. “Goodness of fit” has been taken to new levels of sophistication and specificity as Fox and coworkers (2005) showed an interaction between short “s” alleles and low levels of social support in the family predicting social inhibition.

A further elaboration of this risk paradigm, for adolescents, is to consider how personality traits can be reinforced or reduced by the responses that they evoke from the wider community. Scarr and McCartney (1983) proposed a reinforcing loop that reverberates between the individual, home, and extrafamilial environment. They suggested that genes affect the children’s and adolescents’ behaviors which in turn select or shape the experiences that individuals have outside the family milieu. The loop is completed when these extrafamilial experiences further encourage the same genetic traits (Scarr and McCartney 1983). This model implies that when worried parents report that their adolescent is associating with “bad company,” their concern should not be dismissed. It appears that such affiliations are an influential, separate variable that is associated with delinquency and social adjustment problems later (Kandel 1978). Conversely, involvement with prosocial activities such as the school science club, athletics, a violin quartet, or community volunteer organizations reinforces an adolescent’s socially adaptive behavior. This paradigm also underscores that adolescents’ behaviors affect their parents’ behaviors. For example, teenagers’ behaviors affect parental self-esteem. Self-esteem can be enhanced through pride or lowered through shame, and these changes in turn influence the parent’s actions toward the teenager.

Rutter (1979) has suggested that certain family factors raise the likelihood of adolescents having greater difficulty coping with their impulses and with the rules of society. He cited severe marital discord, large family size with physical or psychological overcrowding, maternal mental disorder, and paternal antisocial behavior as examples of these family risk factors. Furthermore, attending impoverished schools, living in dangerous neighborhoods, and becoming involved in social welfare or correctional institutions such as foster or residential care and juvenile detention facilities add to overall emotional stress. These stressors further jeopardize the adolescent because, typically, they emerge in the context of preexisting biological and psychological risk factors.

A common misunderstanding of the way in which genes influence psychiatric illness is a deterministic view that biology is everything and immutable. One lesson that emerges from these more recent specific gene–environment models is that environmental interventions can moderate or neutralize genetic vulnerability. Thus, research on the mechanisms of disorders opens the way to learn about interventions that might be protective (Rapee et al. 2002, 2005; Mrazek and Haggerty 1994). There is less research on protective factors than on risk factors. One might consider protective factors to be the opposite of risk factors, but this would be an oversimplification. Clearly, physical health, normal or high IQ, and economic advantage play a role. Having above-average intelligence influences school success and facilitates problem solving. Garmezy (1986) stressed three categories of protective factors: “(1) personality dispositions in the child, (2) a supportive family milieu, and (3) an external support system that encourages and reinforces a child’s coping efforts and
strengthens these by reinforcing the child’s positive values.” Garimzy suggested that such adolescents (and children) were more successful in eliciting helping responses from adults and making use of their support. In a similar way, they may also be more successful in making relationships with peers and responding to the support peers offer (Rutter 1989). Such skills increase the chances of parents, peers, and teachers being available to support and guide decisions and challenges that would be difficult to face alone. Better-quality advice and chances to consider the entire set of possible alternatives also increase the likelihood of a favorable outcome. O’Grady and Metz (1987) submitted that adolescents who feel in charge of their lives and know how to obtain help are highly resilient, even when otherwise at risk. The Kauai Longitudinal Study has also reported that the ability to find and use an external support system is a significant protective factor for adolescents who were otherwise considered in jeopardy (Werner and Smith 1992). To this one might add that specific genes capable of counteracting earlier risks can also be triggered by events.

There are suggestions that sex differences may be relevant to resilience too. Girls appear to possess a wider range of coping skills than boys, particularly in forming relationships (Seiffge-Krenke 1990). The community is also a source of protection for adolescents. Scouting or youth clubs, school extracurricular activities, and church involvement provide safe activities for teenagers to acquire friends, find supportive adults, and develop new competencies.

Conclusion
Increasing attention to adolescent development in the past decade has resulted in substantial changes in our understanding of social, familial, cognitive, and biological characteristics of this period. A great deal is still outside our understanding, and tenacious myths about adolescents persist (Offer and Schonert-Reichl 1992). However, new findings place adolescent development into greater harmony with the principles of the preceding developmental epochs. The revised view of these changes during adolescence suggests that they are paradoxically dramatic and yet remarkably similar to those of antecedent periods and much less tumultuous than was once presumed. It is intellectually reassuring to be able to place normal adolescence within the context of the constitutional and experiential past. Increasingly, adolescence emerges as a time in which innate capacities are extended under the influence or guidance of secure familial, cultural, and social supports. Noxious forces from the past and in the present oppose these changes, and their cumulative impact may be greater during this time than at others. It is more accurate to view adolescence as a time much influenced by innate biology and the preceding risk and protective factors, rather than a major metamorphosis triggered by unpredictable interactions between hormones, peer pressures, and the increased separation from parents.

References

The study of adult development is evolving within the context of new empirical investigations. Rich theoretical conceptualizations (Kegan 1982), psychologically informed biographies (Erikson 1963), and empirical cohort-based research (Vaillant 2002) have all contributed to the knowledge base. Although these data have limitations in terms of a lack of specific focus on the experience of different cultural and ethnic groups within this country across time, especially those who have relatively recently immigrated to this country, and an overemphasis on male development, enough evidence has accumulated to suggest well-founded conceptualizations of adult development.

Towards a Conceptual Framework

The central thesis of this chapter is that development occurs in multiple dimensions throughout the course of adulthood. Moreover, adult development is influenced by a wide array of factors including the historical context or times in which individuals live, their economic circumstances, cultural patterns, close intimate relationships, genetic and constitutional factors and history of medical illness, adverse life circumstances, and also positive life circumstances. First, current biological perspectives on adult development are reviewed. Next, the importance of a developmental perspective for understanding serious psychopathology and resiliency is discussed. Last, theoretical perspectives of developmental stages in adulthood are discussed within the context of three longitudinal empirical studies.

This chapter takes place in the context of a rapidly expanding knowledge base about development in general as is evident from other chapters in this volume. Central to understanding development is the core construct of developmental plasticity which emphasizes the capacity of the developing child to flexibly adapt to biological and environmental challenges, be they low birth weight, injury, or medical illness (National Institute of Mental Health 1998). In contrast to earlier genetic theories emphasizing determinism, the growing awareness of how profoundly the environment influences gene expression in a multitude of ways further emphasizes the plasticity of development (Eisenberg 1995). Such a construct emphasizes that at many different points across the life span, individuals can change and grow in response to new challenges. Equally important has been the broadening awareness of the importance of the ecological context, as Uri Bronfenbrenner has emphasized (Bronfenbrenner 1979), in which the child is raised and how attention to various levels in such context can have a positive influence both on children’s development and on adults’ development across the life span. The very structure of a child’s brain across development is profoundly influenced by environmental factors and many of these are susceptible to intervention (Board on Children, Youth and Families 2000, National Scientific Council on the Developing Child 2005). Just as understanding the scientific basis of child development provides the foundation for effective prevention efforts in childhood, so does understanding the multiple influences within a biopsychosocial framework on adult development provide the foundation through which to develop appropriate preventive interventions and clinical approaches. Correspondingly, there is an emphasis on the need to develop programs at multiple levels including throughout adulthood those that foster effective development (Institute of Medicine 1994).

This chapter builds naturally on the preceding review of developmental stages from infancy through adolescence and relies on the integrative framework of Erik Erikson as its organizing principle. Broadly, adult development represents a continued assimilation (the process by which a person takes in and makes sense of material from the environment) and accommodation (a person’s response to changing circumstances within the environment) to both the external world and inner life. Adult development occurs in response to a series of predictable and unpredictable challenges. Such development follows a probable but not invariant sequence as each stage builds on what has gone before. Adult development, although sequential, is not invariably tied to specific ages. For example, puberty in girls may normally occur at age 10 years or at age 16 years. If puberty does not occur, the vicissitudes of menopause will not occur either. Most adults reach puberty, but other stages of adult development may not be attained. Under ideal circumstances, adult development can be conceptualized as an ever-widening social radius.
Challenges in Studying Adult Development
Five factors render our understanding of adult development difficult. First, there must be a recognition that adult development does, in fact, occur. For example, the concept is more accepted in the United States than in much of Europe. Second, longitudinal studies must be understood within the context of cohort effects, cultural characteristics, and historical biases. Third, the observer must maintain a constancy in perspective while documenting development in other matters. Fourth, the duration of empirical longitudinal studies that span the entire range of adult development will, by definition, exceed the productive life of a single researcher. Finally, there is increasing awareness of the need for cultural competence and cultural humility in understanding diverse cultures that profoundly influence both child and adult development within this country and in the larger world (Rogler 1989). It is particularly difficult to incorporate these perspectives in longitudinal studies as many different groups are highly mobile both within a country or in moving between countries whether in urban or rural areas and are difficult to follow over time. Just as understanding how to effectively render culturally competent care is just beginning within medicine and psychiatry, so is understanding the influences of different cultural and ethnic backgrounds on development in individuals over decades (U.S. Department of Health and Human Services 1999).

The most challenging of these issues is that development in adulthood occurs over a much longer time interval than earlier developmental phases. The specific stages of childhood described in earlier chapters may span only one or two years, which renders their detailed documentation much more feasible.

One of the more recent evolutions in the study of adult development is directly relevant, that is, the recognition that both late adolescence and early adulthood constitute a distinct phase of adult development different biologically and in terms of expectations than development from the mid-20s on.

Although the current emphasis on diagnosis within psychiatry has allowed for progress in the study of cross-sectional psychopathology, diagnostic systems have only minimally incorporated developmental principles and, consequently, have obscured the developmental variation that characterizes some disorders (Munir and Beardslee 1999). For example, the diagnostic criteria used to establish depression are identical for children and adults despite the fact that a depressed 8-year-old presents with different symptoms than a depressed 80-year-old, because of differences in psychological, linguistic, and neurological maturation. Also, some anxiety disorders that begin in childhood are chronic and “incurable” at 35 would not meet diagnostic criteria for the disorder at 65.

An additional cause for difficulty in the study of adult development is the fact that individuals are greatly affected by the era in which they live. The profound changes in family structure in the United States in the 20th century provide contemporary illustration. In 1960, 5% of all births occurred to unmarried mothers; by 1988, this figure had risen to 26%. Furthermore, in 1910, only 1% of children experienced parental divorce. In 1993, almost 50% of all children experienced parental divorce during childhood and lived in a single-parent family for at least five years (Carnegie Task Force 1994).

There has been a significant increase in children raised in poverty, and young parents with young children have disproportionately fewer resources. Between 1971 and 1991, although the number of children younger than 6 years old increased by less than 10%, the number of children who were poor increased by 60%. When poverty and single parenthood are combined, the situation becomes even more difficult. Only 8% of children in homes with two parents live in poverty while 32% of children who reside in single parent homes do (Mclanahan et al. 2005). When additional risk factors are added, the situation is even more difficult (Foeg 1998). Finally, there have been significant economic changes over the last three decades with a widening gap between the rich and poor and the concentration of wealth, particularly, among a relatively small percentage of individuals and families. At the same time, poverty in old age has decreased. These factors have a profound implication for the mental and development of adults and children.

Transactional Model
A transactional model facilitates the understanding of developmental evolution. The interactions between constitutional and genetic predispositions in an individual, the effects of early childhood experience and caregiving, and the individual’s interaction with broader society reciprocally affect outcome for a long time period. Although initial transactional models primarily emphasized the influence of factors on the developing child and young adult, more recent models have stressed that the patterns of influence are mutual (Cicchetti and Toth 1995, Sameroff 1989, Sameroff et al. 1998). Endogenous characteristics that develop within a child, adolescent, or adult (e.g., puberty or schizophrenia) can have a profound impact on the environment of the family. As yet, such transactional models, for the most part, have not been able to include longitudinal perspectives on the role cultural variation plays in influencing developmental transactions and different pathways of adult development.

Finally, the need for utilizing caution when considering the certainty of prediction in adult development is demonstrated by empirical studies. Discontinuities are not uncommon in studies of adult development (Rutter 1993, Vaillant 1977) and simple linear developmental lines are often difficult to discern.

In most studies, there are clear correlations between certain childhood and adult characteristics such as intelligence or endomorphy, but these consistencies are less evident as the complexity of the characteristic increases. For example, schizoid children rarely grow up to be schizophrenic adults. In contrast, children with profound mental retardation or autism experience lifelong effects from these conditions. In populations of healthy individuals, the discontinuities are particularly evident and emphasize the degree of change that adults undergo over time. One reason for these changes is the gradual penetrance in adult life of genetic predispositions (e.g., Huntington’s disease, alcoholism, and bipolar disorder). Identical twins are often more similar in personality at age 60 years than they were at age 10 (Bouchard et al. 1990).
Knowledge of adult development has evolved from four sources: (1) theoretical conceptualizations of development, (2) detailed studies of individual lives, (3) empirical examinations of discrete phenomena over time, and (4) most rarely, studies that have attempted to integrate conceptual theoretical frameworks with empirical data. The synthesis of these results provides a heuristic overall framework.

Biological Perspective
A developmental perspective is useful in understanding the biological changes of adulthood (Figure 12–1). Most individuals pass through puberty. For a majority, this leads in turn to the achievement of independent living, sexual intimacy and procreation. By the age of 65 years, an individual has undergone many biological developmental transformations that are quite independent from the decrements of function that result strictly from the aging process. The adaptive responses to the penetrance of genetically controlled diseases such as bipolar depression or alcoholism vary with age and the course of the illness. The biological bases for these differences are less well understood than the equally important environmental forces that affect the individual. Careful longitudinal and cross-sectional studies are required to differentiate genetically determined developmental changes from those that are environmentally determined. For example, although epiphyseal closure is genetically determined, it occurs at puberty, and the onset of puberty is powerfully affected by environmental factors. The languages one speaks are entirely environmentally determined and can be acquired at any age. However, the accent that characterizes speech becomes fixed within a biologically determined period, usually at about the age of 14 years.

Myelinization of the central nervous system continues to occur until the fifth decade (Benes et al. 1994). This may offer a partial explanation for why simple cognitive operations, such as memory and symbol transformation, decline after the second decade, but more complex cognitive operations such as sociational skills continue to improve until the end of the third decade. Continued brain development may explain why sensitivity to simple sensations such as light vision usually peaks at about age 10 years, but reaction time peaks at age 20. Similarly, appreciation of spatial transformations is usually best at age 30 years, whereas the ability to delay gratification probably peaks after age 40. Whereas records for sprinting are held by 20-year-olds, those for long distance races are held by 30-year-olds. Mathematicians and physicists often do their best work before 35 years of age, but philosophers and playwrights often create their finest works after this age. In general, peak cognitive performance usually occurs between the ages of 10 and 40 years and then begins to decline. However, skills of one type often develop to compensate for losses in other areas. For example, 50-year-olds have dramatically better driving records than do 20-year-olds. In contrast, suicide becomes an increasingly high risk with increasing age.

There are predictable developmental changes in Stage 4 and rapid-eye-movement sleep (Roffwarg et al. 1966), electroencephalograms (Woodruff 1978), extrapyramidal symptoms, and brain neurochemistry (Weinberger 1987), but the significance of these changes is not known. For example, extrapyramidal symptoms after administration of neuroleptic agents at age 20 years are quite different from those at age 60 and appear unrelated to brain impairment. The initial manifestations of the gene responsible for Huntington's disease vary with age.

In the locus caeruleus between ages 40 and 60 years, tyrosine hydroxylase, which is the rate-limiting enzyme in the synthesis of norepinephrine, declines while the activity of monoamine oxidase, the rate-limiting factor for the breakdown of norepinephrine, increases. These changes suggest that the activity of the locus caeruleus may be significantly attenuated in the middle years (Roose and Perdes 1989).

Biological Development

18 + years

- Continued myelinization of the central nervous system

- Tyrosine hydroxylase and monosereine oxidase levels decline in locus caeruleus

- Steady decline in male sexual function

- Menopause

  - In women, endogenous androgenic hormone production increases relative to estrogen
  - In men, estrogenic hormone production increases relative to endogenous androgenic hormone

  - General loss of muscle mass
  - General memory loss
  - Decreased vital capacity
  - Decreased vision
  - Emergence of certain profound neurological disorders

Figure 12–1 Biological development from age 18 years through adulthood.
In terms of adult development, it is important not to confuse healthy aging with the results of injury and disease. After age 55 years, there is a considerable decline in a variety of biological functions, including a general loss of muscle mass, loss of memory, decreased vital capacity, and diminished vision, as well as the emergence of certain profound neurological disorders such as Alzheimer's disease. In some elderly persons, these deficits may reflect disease rather than developmental decline. Some octogenarians can carry out almost every cognitive and physical function as well as an average 40-year-old despite some loss of abilities in memory and flexibility. In addition, the cross-sectional evidence suggesting that general intelligence declines between ages 20 and 70 years is probably an artifact of cohort effects on educational opportunities as opposed to biological processes. Prospective studies do not support such declines in general intelligence (Schaie and Parham 1977).

During puberty, predictable shifts occur in sex hormones that are known to affect cerebral functioning. Particularly in women, changes in the reproductive system are marked during the years of adulthood. In early adulthood, most women menstruate and are able to bear children. Between the ages of 45 and 54 years, a series of endocrine changes accompany menopause, including changes in the balance and production of female hormones. After age 50 years in women, endogenous androgenic hormone production increases relative to estrogens. Although wide individual differences exist, these hormonal changes may facilitate a shift toward increased female dominance that occurs within some couples after the age of 50 years (Guttman 1977). For men, no single biological change occurs, but there is considerable evidence of decline in testosterone production and sexual functioning.

The relative importance of sexual life compared with other facets of intimacy can increase at any point between 15 and 65 years of age. Although there is a steady decline in male sexual function from ages 20 to 70 years in terms of the mean number of orgasms per week, this is not true for women. Studies have shown that women become increasingly orgasmic with age in their third and fourth decade.

The importance of a developmental perspective in dealing with fundamental psychopathology has been illustrated by using schizophrenia (Weinberger 1987). The psychopathology of schizophrenia can best be explained by a developmental hypothesis that acknowledges the underlying brain abnormalities that are present long before the disorder of schizophrenia appears in young adulthood. During childhood and adolescence, the individual with these biological abnormalities appears developmentally normal. It is in early adulthood that predictable stressors may place high demands on these vulnerabilities, which leads to the expression of symptoms. In a somewhat different model, the hypothesis has been advanced that schizophrenia emerges in adolescence due to the excessive pruning of neuronal structures in adolescence (see Chapter 19).

Similarly, studies of Parkinson's disease suggest that both the general symptoms and the monoamine oxidase concentration in the globus pallidus change depending on the age at onset of the disease (Robinson et al. 1977). Various metabolic diseases and brain disorders (e.g., traumas, tumors, and injuries resulting from war) are similarly affected by age at onset. The same underlying structural abnormality may lead to different symptoms depending on the developmental stage of the individual. In short, the manifestations of disorders of the nervous system are heavily influenced by the developmental level of the adult.

**Developmental and Cohort Effects**

The importance of a developmental perspective is emphasized by studies of substance abuse and addiction across the life span. Secular trends have a strong impact on drug use. Different drugs have been “in fashion” during different decades. Consequently, it is important to separate social trends and cohort effects from more universal patterns of adult development. Despite these difficulties, there is substantial evidence that adults at different life stages use drugs for different reasons. In adolescence and young adulthood, drugs are often used for novelty and excitement. In middle life, drug abuse is more likely to be linked to social and family rituals. Finally, drug abuse is often the result of an effort to produce calm and to reduce the anxiety-producing effects of novelty and change in late life (Arnett 2000).

Typically, most stimulant drug use occurs before the age of 20 years. Specifically, inhalants, such as glue (in glue sniffing) and tobacco (in cigarette smoking), are among the first drugs to be abused. These rapid-acting agents are more likely to produce dependence in young adults. Furthermore, by adjusting their behavioral repertoire, young adults often use alcohol and barbiturates in ways that create excitation. In contrast, the peak use of sedative drugs occurs after age 45 years when these drugs are used not to party but to calm (Figure 12–2). Cessation of illegal drug use by adults in midlife appears linked to emotional maturation, which allows for greater tolerance of depression and the replacement of drugs with intimate relationships (Vaillant 1996).

More generally, there is a developmental pattern to the onset of different psychiatric disorders. Antisocial behavior is more common in adolescents, schizophrenic symptoms in young adulthood, and affective disorder in middle life (Weinberger 1987). There is evidence that the 12-month prevalence of psychiatric disorders declines across early adulthood. Tanner et al. found declines in 12-month prevalence of anxiety and substance use disorders over the third decade of life in a community sample. In contrast, the rate of depression during a lifetime increased from 8.8% at age 21 to 31% at age 30 emphasizing the need to look at different disorders across different developmental epochs and heightening a focus on the internalizing conditions in early and mid adulthood.

Elder illustrated a cohort effect on adult development by examining individuals who grew up during the Great Depression (Elder 1990). In a prospective study of children at the Institute of Human Development at Berkeley, California, USA, he demonstrated the differential effects of World War II and the Great Depression by following a 1920s cohort and a 1930s cohort from birth into adulthood.

In the 1920s cohort, boys grew up to be more successful and competent, whereas girls fared relatively poorly. Conversely, in the 1930s birth cohort, the boys did less well than the girls. Purportedly, financial privation affected prepubertal children differently from adolescents. Elder provided a cohort-based explanation that considered a variety of social, economic, and psychological
Risk Factors, Protective Factors, and Resilience

Some developmental challenges that occur during adulthood, such as child-rearing, are also risk factors for the onset of affective disorder. Studies show that mothers who have several children younger than the age of 6 years and who lack adequate social and financial support are at particularly high risk for the onset of major depressive disorder (Weissman et al. 1987b). Evidence has accumulated that multiple risk factors occurring together including poverty, exposure to violence, social isolation, and lack of access to resources along with depression, place individuals in families at high risk for depression and other negative outcomes (Institute of Medicine 1994).

Several studies of children at high risk for depression have followed these children into adulthood. Quite high rates of depression in their offspring have been reported and continue to increase as these young people age (Weissman et al. 1999). Thus, a developmental perspective on the emergence of difficulties in adulthood should include identifying individuals who experienced disorders in childhood and those at high risk for disorder. Also, it is now clear that grandparents’ illness as well as parents’ illness contribute to the multigenerational transmission of depression (Weissman et al. 2005). Thus, consideration of risks across several generations is needed. At the same time, evidence has accumulated that grandparents can be an important resource for both children and young adults as they develop and mature. Understanding both risks and protective factors across development will continue to evolve.

Resilient individuals do well despite being at high risk for negative outcomes. There is convergent evidence identifying a set of factors that contribute to resilience. In seminal work on resilience, Garmezy et al. (1984) have proposed broad categories of such protective factors, including self-esteem, positive social orientation, family cohesion, and availability of an external support system. Luthar et al. (2000) have produced a useful review and conceptual framework for understanding resilience. Understanding resilience is one essential component of developing effective preventive intervention strategies. Such strategies often aim to encourage those resilient characteristics identified in unusually resilient individuals in the entire group at risk.

In adulthood, resilience depends on the ability to find, use, and internalize social supports. Throughout the life span, maturity of ego defense is an important characteristic of resilience. The specificity of stressors appears to be less important than the relative number of risk and protective factors. This suggests that the number of

protective factors minus the number of risk factors provides a crude but useful index for predicting outcome. Luck, the timing of the stressor, and the individual’s fundamental sense of self-esteem and self-efficacy also affect outcome (Vaillant 1993).

Data from a number of ongoing longitudinal studies illustrate the different facets of resilience over time. Werner and Smith (1992) conducted a 30-year study on the island of Kauai and followed up infants from different cultural backgrounds into adulthood. Many were at high psychosocial risk because of family dysfunction and poverty, but approximately one fifth of these high-risk youngsters demonstrated good adult adjustment. The protective factors were categorized as those within the child, within the family, and within the environment.

In terms of factors related to the individual child, the absence of distress in early life and good sleeping and eating habits were important protective factors. Similarly, being affectionate (for girls), being active (for boys), the absence of behavior problems at age 10 years, and the presence of high intelligence were associated with good adult outcomes. Other studies have confirmed the importance of positive temperament, above-average intelligence, and sociability (Werner and Smith 1992, Rutter 1985). The presence of a close and caring relationship with at least one parent or other caregiver during early childhood has been shown to enhance resiliency (Werner and Smith 1992, Werner and Smith 1982). More recently, attention has focused not just on the achievement of resilience at a particular stage but on the mechanisms by which adolescence and adults become resilient and on the processes which underlie such resilience (Luthar et al. 2000). Just as risk factors interact across time, so does the presence of protective factors acting in combination with one another.

Research also emphasizes the importance of the ecological framework or multiple layers of influence from family, neighborhood, community, and even social policy in determining resilient or non-resilient outcomes at a particular developmental stage (Bronfenbrenner 1979).

Within the family, high educational level of the opposite sex parent and warm relationships with both parents proved important. The presence of rules and structures in the household strongly supported adolescent development, as did having mothers who worked. Families with four or fewer children and with at least a 2-year interval between children were also protective (Werner and Smith 1992).

In terms of protective factors within the community, relationships outside the family and external support systems such as churches, youth groups, schools, and recreational activities were important (Bronfenbrenner 1979, Jones and Offord 1989, Werner 1989). Good secondary schools also had a positive effect (Werner 1989, Rutter et al. 1970).

In adulthood, second-chance opportunities occurring at major life transitions were protective. These included marriage or entry into a long-term relationship, the birth of a child, finding a supportive employer, entering the military service, or joining a church group (Werner and Smith 1992, Jones and Offord 1989). More generally, two kinds of protective factors in adulthood have been identified: those that arise from social supports and personality attributes that affect the ability of an individual to master stress (O’Grady and Metz 1987). Also, the capacity for self-reflection and self-understanding is an important component of resilience in adolescents and adults facing adversity (Beardslee 1989). Moreover, understanding these protective factors have important and direct preventive intervention implications, for example, making certain that there are second chance opportunities for all groups in the population around transitions or encouraging the capacity for self-reflection and self-understanding through appropriate preventive intervention strategies.

**Young Adulthood as a Distinct Developmental Stage**

The Study of Young Adulthood has advanced the conceptualization of resilience considerably (Masten et al. 2004) and has focused particularly on the transition to young adulthood as a possible time for the emergence of strengths. There is increasing awareness that the transition to adulthood is a distinct developmental stage and presents both challenges for young adults moving through this phase and opportunities, in particular, a chance to develop new relationships and identifications (Arnett 2006). Much less attention has focused on the transition to adulthood in youth growing up in contexts of adversity.

Arnett first used the terms “emerging adulthood” to indicate the period 18–25 years which included exploration and growth and was distinct from both adolescence and early adulthood (Arnett 2000). He further (Tanner 2006) indicated defining elements as explorations of identity in the areas of love and work, being self-focused, and explorations of possibilities and opportunities to pursue. In Tanner’s conceptualization (Tanner 2006), there is “a recentering of relationships,” in particular, family relationships. Accomplishment of this stage is often quite heterogeneous. For many young adults, there is a considerable freedom without strict requirements for their behaviors (Gladstone et al. 2006). Others have also advanced the view that the transition to adulthood is important and, in fact, this generation is different than the past in being less unified and, for some, in carrying higher aspirations. American society has also delayed expectations which, in turn, has led to a prolonged developmental phase.

Shanahan (2000) has observed that within the individual’s life, there is a greater change and more variety in social roles in young adulthood than at any other time. Correspondingly, there seems to be a decrease in mental health problems for some groups of young adults (Tanner et al. 2007). Several psychologists have observed that the experience of transition to adulthood occurs in a balance between autonomy and relatedness (Best et al. 1997, Eccles et al. 2003). The health of emerging adults is tied to their families (Gladstone et al. 2006, Kaimal 2007).

Fuligni and Pedersen (2002) have argued that remaining related to parents is a key task of emerging adulthood and may indeed set the stage for later caregiving. They found that responsible behavior towards family members increased following high school and, more generally, relationships with family members increased.

In a study of 205 individuals tracked into early adulthood, Roisman et al. (2004) demonstrated the predictive connections between three tasks of late adolescence and young adulthood: academic attainment, quality of friendships, and absence of disruptive conduct symptoms.
They also examined two domains that they hypothesized emerge during this area: romantic competence and work competence. Romantic competence means being able to function effectively in an intimate relationship. Work competence means accomplishing appropriate tasks in the area of work. In following these individuals until age 30 and combining reports from the participants, the parents, and clinical ratings by judges, they found that the salient tasks from age 20 predicted within domains success ten years later with one exception that both conduct and academic competence at 20 predicted absence of conduct problems and rule abiding behavior at 30. They also looked at resources and resilience in the transition to young adulthood, again combining multiple domains as had the earlier Werner and Smith work. They found that success in both early and young adulthood related to core resources that were present in childhood, namely, higher IQ, good parenting quality and socioeconomic status and also a set of within person adaptive resources that included the capacity to be planful, to have motivation for the future, to have a sense of autonomy and coping skills, and also the presence of adult support. This work suggests important domains for possible preventive interventions for youth at high risk across this developmental transition. It also illustrates the continuity between childhood and early adulthood. These investigators plan to follow these young people into middle adulthood which will further our understanding of this important stage.

Changes in the demographics have also influenced this stage of young adulthood (Tanner et al. 2007). In 1970, the median age of males and females at the time of marriage was 22.8 and 20.3, respectively, whereas today, it is 26.8 and 25.1, respectively. This has profound implications for development. Similarly, in 1970, the proportion of high school graduates who enrolled in college was about 51.8%. This increased to 63.3% in 2000. Moreover, the transition of youth into the workforce has become much longer and more unstable. The demand for service jobs outweighs the need for jobs in manufacturing. Certain areas like highly technological endeavors have seen the increase and also highlighted the need for a more educated workforce. All of this has contributed to a change in adult role with a greater focus on obtaining additional education. Part of the amount of formal education and the delay has led Arnett (2000) to formulate the concept of emerging adulthood as described previously. In some ways, identity formation in Eriksonian terms may be viewed as being prolonged and much more the task of young adulthood. Arnett has also added that in addition to tasks of love and work, another goal is the attainment of an appropriate enduring worldview.

Another important characteristic of contemporary emerging adulthood is the rapid pace of change and a set of challenges not well described in previous epochs. One of the interesting challenges in work on the study of adult development in the future will be to see how these new changes influence outcomes. Robert Blom (National Research Council and Institute of Medicine 2006) of Johns Hopkins recently described a set of firsts for America’s youth and young adults. Specifically, Blom posits that today’s youth will be the first generation to:

- live through instantaneous communication that is available throughout the world,
- who will spend a portion of childhood in a single parent household,
- have the threat of AIDS over their entire lives, and
- have watched an entire American city destroyed, that is, New Orleans in the wake of Katrina.

Blom’s point is not at all that prior generations did not face difficult or even more difficult challenges but that the nature of these challenges will shape the experience of young people. How these particular events singly or occurring together will have an influence on this generation’s development remains to be investigated, but there is no doubt that these events will influence the course of development. As one example, how will the various kinds of much more rapid technologically supported communication, such as instant messaging and e-mail, influence the development of intimate relationships? This is a question that has yet to be answered but one with important implications for understanding both development and the influence of communication and relationships on development. Another is does the widespread use of instantaneous communication devices by children and adolescents affect their overall physical and mental development either positively or negatively in significant ways?

Our emphasis in the preceding section on the importance of the emergence of young adulthood speaks to the addition of this distinct stage to the creation of developmental schemas. Furthermore, it is important to recognize that while the current generation is the first to experience these new challenges, the trajectories of development of all generations are influenced.

**An Integrated Model for Adult Development**

The best model for understanding development is one that integrates clearly defined behavioral tasks and functions in the external world, such as having friends, with innate and developing capacities within the individual, such as coping skills. Vaillant and Vaillant (1981) studied a sample of adolescent boys until age 50 years. These boys had been at risk because of poverty and recent immigrant status. They found the most important predictor of success to be “competence.” Clausen (1993) similarly described “planful competence” as a core integrative construct that predicted successful adult outcome. Competence reflected the presence of regular part-time work, performance of household chores, participation in extracurricular activities, good school grades relative to IQ, and ability to plan.

In the study by Vaillant and Vaillant (1981), competence measured what the individuals did, not what they reported about their feelings. Examination of adult outcomes in objective behavioral terms led to three important findings. First, the capacity to work in early adolescence was strongly correlated with good mental health in midlife. Second, the boys who were most successful in adolescence in terms of competence were much more likely to be successful in adulthood, in terms of both their paid jobs and their capacity to have relationships with others. Third, the presence of positive attributes in the family environment was more predictive of outcome than was the presence of negative attributes. Similarly, the positive presence of
planful competence outweighed the presence of negative factors.

The complex interactions between risk factors and protective factors and the emergence of resilience over time are illustrated in a different way by two investigations conducted in London. The study by Quinton and Rutter (1988) of difficulties in parenting provides an illustration of complex development transitions. This study followed up a group of girls who had been placed in residential or group homes as youngsters. Those girls who, after leaving the residential home, entered positive family environments were more likely to make positive decisions later in life, such as in the selection of a supportive spouse. They also developed better parenting skills. Similarly, those who had good school experiences were more likely to demonstrate planning in terms of career choice and marriage partners. On the other hand, the youngsters who did not have positive family experiences tended to marry quickly and to make poor choices in life. These women more frequently divorced and displayed difficulties in parenting their own children. Thus, the capacity to plan emerged as crucially important in making choices about marriage partners. This, in turn, was strongly related to success in child rearing.

Brown and Harris (1989) demonstrated that a complex interactive model of risk and protective factors was associated with the onset of depression in a group of women living in London. They found that the absence of close confiding relationships in adulthood coupled with the presence of unusual stresses preceded depression in women. Focusing on earlier events, Rutter (1981) demonstrated that it was the loss of care for the child and the degree of the disruption in the child’s life after the death of a parent that predicted a negative outcome rather than parental loss per se.

### Developmental Formulations of Adulthood

Most theorists believe that development involves an increase in cognitive and affective differentiation that leads to a greater capacity to relate to the environment. The observations by Piaget (1932) of the dual processes of assimilation and accommodation and the invariate sequence of stages in the development of intelligence have supported this fundamental belief. He also described the stages in the development of intelligence and the cognitive structures or schemas that underlie the learning paradigm. Individuals progress from one cognitive stage to the next through periods of disequilibrium. The process of equilibration involves coming into balance in the new phase.

Piaget’s approach has been applied in adults to moral development (Piaget 1932), the development of self-understanding (Damon and Hart 1982), and the development of interpersonal understanding (Selman 1980). Kohlberg (1973) delineated six stages of moral development: Stage 1, a pre-moral level with a punishment and obedience orientation; Stage 2, a naive and straightforward hedonism; Stage 3, a level involving conforming to avoid disapproval; Stage 4, a level entailing conforming to avoid criticism by legitimate authorities in the development of guilt; Stage 5, morality of contract in which there is an agreement to maintain and respect impartial laws; and Stage 6, morality of individual principles in which the individual conforms to avoid self-condemnation. Processes similar to those described by Piaget were hypothesized to occur in the development of each stage. Although these stages of moral development provide some support for a stage sequential perspective, this work has been criticized for not addressing gender-specific differences.

A second model, based on the principles of ego psychology, is compatible both with the developmental frameworks presented in this chapter and with the work of Loevinger (1976). This model attempts to describe and characterize inner states, processes, and functions that manifest themselves in a wide array of behavioral situations that correspond to behavioral functioning. Ego defenses and ego maturation are viewed as critical organizing constructs across the life span. This formulation of the ego proposes a mediating function in the inner life that facilitates the completion of complex behavioral tasks. In psychoanalytic terms, the ego resolves conflicting impulses and, in contemporary terms, it performs executive and organizing functions such as focusing attention.

Differences in ego functioning explain the mechanism by which individuals cope with conflict or stress. Longitudinal studies of development have found conceptualizations of increasing capacities of the ego and maturing defensive structure to be useful (Vaillant 1993, Haan 1977). Vaillant’s work illustrates a heuristic framework of ego development parallel to shifts in diagnostic domains. Ratings of defenses were based on both objective behaviors and awareness of inner states (Rutter 1993, Vaillant 1993). The “immature” defenses, which are common to character disorders, include denial through fantasy, dissociation, projection, passive aggression, hypochondriasis, and acting out. There is also a set of “neurotic” defenses including intellectualization (isolation,

*Diagnosis assumes that conscious representation of the conflict was carried to pathological extremes and that the other criteria for the diagnosis were met. DSM-III, Diagnostic and Statistical Manual of Mental Disorders, Third Edition.

undoing, and rationalization), repression, displacement (including phobias and conversions), reaction formation, and disassociation (neurotic denial and counterphobia (Weinberger 1987) (Table 12–1).

Finally, there are “mature” defenses such as altruism, sublimation, suppression, anticipation, and humor. These defenses are particularly relevant to the adulthood stage because many of them are thought to appear only in late adolescence or adulthood. Altruism entails doing for others as one would have done for oneself. The person engaging in altruistic behavior is at least partially gratified, and such behavior contributes to self-efficacy. Sublimation allows the expression of intense emotion without either adverse consequences or loss of pleasure. Suppression involves the semiconscious decision to postpone paying attention to a particular inner impulse. Anticipation involves realistic and effective planning for the future rather than denying and incorporates thinking and planning about affective issues as well as cognitive ones. All of the mature defenses integrate sources of conflict and thus do not involve characteristic modes of self-deception. Unlike other defenses, mature defenses allow subjects to experience themselves, their relationships, their ideas, and their feelings fully and without ignoring important parts of either external reality or their internal lives.

The relative maturity of defenses was ascertained by comparing the proportion of an individual’s mature defenses with the proportion of her or his immature defenses. Two major findings emerged. Immature defenses were negatively correlated with good adjustment and positively correlated with psychopathology. The reverse was true for mature defenses. They were associated with health, whether health was defined as the presence of successful objective life adjustment, the absence of psychopathology, or the achievement of subjective satisfaction. Men characterized by passivity, pessimism, self-doubt, fear of sex, and dependence were more likely to use immature defenses. In general, adolescents also utilized immature defenses, whereas adults in middle life typically used mature defenses. Between the ages of 15 and 45 years, there was a gradual evolution in both of the longitudinal samples from the use of immature defenses to the use of mature defenses (Vaillant 1993, Haan 1977). Figure 12–3 provides a graphical representation of changes in the use of defenses over time. As with Kohlberg’s data, such evidence strongly suggests a maturational process that occurs during the course of adulthood.

**Eriksonian Model of Adult Development**

Whether there are stages that characterize adult development in the same way that there are stages in childhood and adolescence development is unlikely. Nevertheless, adults manifest a developmental sequence of task mastery illustrated by Erikson’s model that has been found to be useful (Erikson 1956, Havinghurst 1972). These tasks have the advantage of being less ethnocentric than either an individual-centered stage sequential model...
The adult life cycle is presented in Figure 12–4 as a series of stages (Havinghurst 1972). A modification of Erikson’s model of a more appropriate construct than stage of development suggests that a term such as Havinghurst’s developmental task is more useful than a defense-centered model. Erikson’s model suggests that the appreciation of both the meaning of the adult ego development lies in the appreciation of both the relative complexity and the inner threat of the tasks and commitments that must be mastered. The twin anxieties of young adulthood involve the abilities to commit to one person and to commit to one job without sacrificing autonomy. Older adults, having mastered these tasks, may serve as mentors in the process.

There is correspondence between the accomplishment of tasks in the external world, such as maintaining a long-term intimate relationship, and ego development. This framework is valuable not only for organizing the unfolding of development in normal individuals but also for providing a useful framework for understanding how psychopathology may affect development at different stages.

In the empirical studies, those individuals who achieved generativity almost always had also evolved to stages of identity formation, achievement of intimacy, and career consolidation. This proved true both for men and for women (Vaillant 1993).

Erikson’s task of identity versus identity diffusion, Stage 5, reflects mastering the last task of childhood which is the sustained separation from social, residential, economic, and ideological dependence on one’s family of origin. Such separation derives as much from the identification and internalization of important childhood figures as it does from the ability to master modern life. Identity is not just a product of egocentricity, of running away from home, or of marrying to escape the family. There is a world of difference between the instrumental act of running away from home and the developmental task of knowing where one’s family’s values end and one’s own values begin.

Men and women who fail to reach a sense of identity do not achieve independence from their family of origin, or they remain dependent on institutions (Stage 5). In middle life, such individuals remain dependent on others and never commit themselves either to occupational specialization or to sustained intimate friendships. Many individuals diagnosed as having schizophrenia with stable community adjustment fall in this category.

Mastery of the task of intimacy versus isolation (Stage 6) serves as the gateway to adult development. Intimacy is defined as living with another person in an interdependent, committed, and intimate fashion for years. Although marriage, heterosexuality, and orgasm are not necessarily criteria for intimacy, intimacy is initially achieved most often with a spouse. Adolescents and adults with pervasive developmental disorders are usually incapable of close mutual interdependence. For many young adults, mastery of interpersonal intimacy is a major focus of psychotherapeutic treatment.

The creation of a stage between intimacy and generativity reflects the importance of achieving a stable career identity. The construction of this stage distinguishes the development of identity within one’s family of origin from the development of identity within the world of work. The internalized (usually familial) mentors important to achieving identity are rarely the same as the (rarely familial) mentors important to achieving an identity in the world of work. This task has been described as career consolidation, which involves the achievement of vocational identity that, like intimacy, reflects reciprocity. Put differently, the task of career consolidation is often accomplished after the achievement of intimacy but is characterized by commitment,
compensation, contentment, and competence. In behavioral terms, this task involves making a clear, specialized career identification and measured by personal satisfaction and appreciation by others. These four concepts distinguish a career from a job. Career consolidation involves the transformation of preoccupation with self into a specialized role valued by both self and society. Just as the task of intimacy includes the mastery of attachment, so mastery of this task involves the modulation of anger.

One of the tasks of mature adult development is to accommodate to societal imperatives rather than to compensate for them. The study by Broverman et al. (1972) showed that both men and women attributed a specific cluster of traits including independence, rationality, and self-direction to the ideal man, independent of their level of education. Both sexes attributed a different cluster of traits such as warmth, emotional expressiveness, and relatedness to the ideal woman. Prospective studies suggest that by midlife a major developmental task for women is to achieve the traits of independence, rationality, and self-direction (Vaillant 1977, Guttman 1977). Similarly, it becomes equally enriching for men in midlife to achieve warmth, emotional expressiveness, and relatedness (Rogler 1989, Guttman 1977).

Selfless generativity (Stage 7) reflects a clear capacity to care for and guide the next generation. Generativity means assuming sustained responsibility for building the community and for the growth, well-being, and leadership of others. It can entail serving as a consultant, guide, mentor, or coach to young adults in the society. In Figure 12-4, we have split off certain facets of Erikson’s concept of generativity and relabeled them as Stage 7a, keepers of the meaning. Generativity and its virtue, care, require taking care of one person rather than another (Erikson 1963). Keeper of the meaning and its virtue, wisdom, involve a nonpartisan and less personal approach to others. Thus, the tasks of a generative coach or partisan parent of adolescent children are vastly different from the tasks of a Supreme Court judge or chair of a historical society.

The generative individual cares for others in a direct, future-oriented relationship such as teacher cares for a student. In contrast, the keeper of the meaning speaks for past cultural achievements and guides groups, organizations, and bodies of people toward the preservation of traditions. Care and justice, as Gilligan (1977) underscored, have always been different dimensions of development. However, the term wisdom is preferable to justice, for it is less value-laden and, hopefully, synthesizes care and justice.

The final state, integrity, may be compared to putting a garden to bed for the winter. Life-review facilitates coming to terms and accepting the past. Planning legacies involves appreciating that families, like gardens, go on living after one’s death. At the end of life, spiritual life may deepen and become more meaningful than the journey depicted in the spiral staircase model. During the life span there appears to be an oscillation with a still longer amplitude than the journey depicted in the spirial staircase model. At some point in life, there are suddenly more yesterdays than tomorrows. At this point one seemingly retraces the steps one has climbed. If the steps from infancy through childhood to adolescence lead sequentially to mastering one’s body, one’s external environment, and, finally, one’s emotions, then from age 40 years to senescence the steps lead in the reverse direction. Like the adolescent, the 40-year-old in crisis struggles with feelings; like the 10-year-old, the 60-year-old struggles to resist the changing times; and the 80-year-old, like the toddler, is preoccupied with an unruly, unsteady body. Neugarten (1964) has written that if 40-year-olds “see the environment as one that rewards boldness and risk-taking, 60 year-olds seem to see the environment as complex and dangerous, no longer to be reformed in line with one’s own wishes and to see the self as conforming and accommodating to outer world demands.”

Another area of importance is a growing awareness that parenting itself can have a very positive developmental influence on adults who are parents (Beardslee 2003). While most formulations, as Erickson does, acknowledge raising children as one of the important tasks of generativity and relating to one’s own children and other young people is needed in later stages, much more attention needs to be focused on understanding how parenting can positively influence development. As one example, evidence has accumulated that for parents who are depressed, a preventive intervention approach which incorporates a focus on effective parenting and fostering resilience in their children has considerable merit (Beardslee et al. 2003, Beardslee et al., in press).
Grief

Although it is believed that as one ages, one becomes more accepting of death, increases in age also increase the likelihood of experiencing the loss of a loved one or a family member. Bereavement, or grief, usually occurs after such a loss. Uncomplicated grief is believed to proceed through a series of anticipated stages (Schulz 1978). The initial stage, which occurs during the first few weeks after the loss, is characterized by feelings of shock and disbelief. The second or intermediate phase takes place during the first year after the loss; it is distinguished both by feelings of loneliness and by thoughts about the death, why it happened, and how it could have been prevented. Usually by the beginning of the second year after the loss, the individual begins the recovery phase; during this time the individual begins to seek out social situations and moves on with life (Dworetzky 1995, National Institute of Mental Health 1988). Lehman et al. (1987) pointed out that little is known about the actual duration of grief, and in their studies of parents and spouses who were experiencing unexpected loss, grief often continued to be experienced many years after the loss.

Unexpected or sudden deaths often result in more severe and long-lasting periods of grief than those that were anticipated (Lehman et al. 1987, Parkes and Weiss 1983, Stroebe and Stroebe 1987). Death of one's spouse, regardless of the nature of the death, can have a significant impact on the health of the individual, with it “not being uncommon for the remaining spouse to become seriously ill or to die within two years (Dworetzky 1995, Stroebe and Stroebe 1987).” A gender difference in the period of greatest risk has been observed, with widowers being at increased risk for the first year after loss and widows during the first 3 months (Mellstrom et al. 1982). Widowers who remarry appear to have lower mortality rates than those who do not (Helsing et al. 1982).

The effects of loss do not appear to lessen with increased age. Lesher and Bergey (1988) found that the loss of a child resulted in a number of negative effects in elderly bereaved mothers. These mothers experienced high levels of “psychological distress” as well as changes in “health, functional activities, family cohesion and psychological well being.” The authors pointed out that not only does the loss of a child have an impact on the older individual’s sense of life order, but it may also have a strong impact on the quality of their life. This can be due to the assistance that the child could have provided or to the decreased contact with their deceased child’s spouse and/or children that can result.

As individuals pass from childhood through adolescence and into early adulthood, most have developed a belief that death is irreversible, final, and inevitable (Dworetzky 1995). Kubler-Ross (1969) has identified five stages that occur when individuals are confronted with death: (1) denial and isolation, (2) anger, (3) bargaining, (4) depression, and (5) acceptance. These stages are useful in understanding the experience of dying, but it should be noted that they do not necessarily occur in a particular order and that all stages may not be experienced by every individual. For example, an individual’s response to death may be influenced by their age: those of a younger age may be more likely than older persons to experience stages of denial and anger (Pattison 1977).

Transitions and Developmental Crises

Several investigators prefer to chart adult development in terms of transitions and developmental crises. In some sense, transitions are a by-product of normal development. Certainly, the process of adult development is more than the achievement of chronological landmarks such as one’s graduation, first job, marriage, and first child. Development creates transitions, and transitions then influence development.

The crises associated with transitions often have more to do with three nondevelopmental factors than they do with the process of development. The first factor is psychopathology. For example, individuals who have a particularly troubled adolescence are also likely to have a particularly troubled middle life. Similarly, a tendency to serious depression makes almost any change a crisis. However, community studies of people during adolescence and middle age suggest that such assumptions of inevitable developmental crisis are unwarranted (Farrell and Rosenberg 1981, Offer and Offer 1986).

The second factor associated with crisis during developmental transitions involves poorly culturally mediated changes in role. For example, an uncelebrated retirement or a perfunctory civil marriage ceremony may lead to greater instability of adjustment and to later crises. Nonindustrialized cultures frequently ritualize adolescence, menopause, and old age more effectively than do modern industrialized cultures. Smooth transitions appear to be facilitated by cultural, ritual, and sacramental celebrations.

The third factor associated with the crises of life transitions occurs when the transitions take place outside of the appropriate temporal sequence. Widowhood is a greater developmental crisis at 40 than at 80. Menopause may be a crisis at 30 years of age but a welcome fact of life at 50. In contrast, the death of a child is always a crisis because it runs counter to the expectations of adult development.

The Enduring Importance of Identity Formation

In reflection on the course of development, several points deserve emphasis. The first is that within the various Eriksonian stages, an emphasis on identity formation and identity is the key to each stage. A firm sense of personal identity is a critical achievement of adult development. This identity can change as the individual grows and develops, but identity nonetheless provides both an internal anchor and a stable way of relating to others in the world. Erikson emphasized that the adolescent process of identity formation ends only when an individual develops a new kind of identification and, indeed, long-term commitments both to others and to work. Furthermore, before an identity is formed, there is often a psychosocial moratorium during which an individual postpones making life choices. Erikson emphasized the dynamic interaction between the inner sense of self and the manner in which individuals have responded to and dealt with those around them. In simple terms, youngsters evolve from being dependent on their parents and going to school to maintaining jobs of their own, functioning independently, and developing close intimate relationships. In broader terms, mastering the task entails mastering internal conflicts so as to be able to engage in working and loving. Erikson emphasized that identity
formation is not simply an internal process of selecting identification during childhood but a process through which others often “through sub-societies identify the young individual” (Erikson 1956)."

Clinical Implications
From a clinical perspective, it is well worth determining the fundamental identity of the person under consideration and where along the various stages of adult development the individual falls. A second consideration is how the individual deals with her or his own children. The stages of adult development are closely tied to functions related to child rearing. In the stage of career consolidation, one component is the need for the provision of adequate resources to raise a family. One area that needs much more attention is how being a parent can actually foster the growth of maturity and development in adults and that for many adults, the most meaningful and generative relationships they have is with their children. Moreover, a focus on parenting and being successful as a parent can be very helpful to adults who face unusual risks because of experiencing multiples of adversities or major mental illness (Beardslee et al. 2003, Beardslee and Knitzer 2003).

In the later stages, characterized by generativity, individuals proceed from being concerned mainly with their own children to becoming concerned about broader issues such as the next generation in general. This occurs as their own children become parents and as people of the next generation assume leadership positions and become mentors and teachers. The penultimate stage, keeper of the meaning, includes being a wise grandparent or, in figurative terms, embodying family wisdom and cultural wisdom.

Mastery and integrity, the last stage of life, is often facilitated by the clinician or hospice worker, being attuned to the need for life review, guided as to biography and a chance to examine one’s deeper spirituality.

Understanding what the normative developmental tasks that children of different ages face and how well they are accomplishing them compared to their peers are important components of evaluation for children and adolescents. This also applies to the evaluation of adults. Thus, for example, a crucial normative developmental task for young adults is mastering intimacy with others, or for older adults, becoming generative. Evaluating patients on how they are accomplishing these tasks in the context of the difficulties they present for care is important. Also, how individuals have successfully accomplished the challenges of prior developmental stages is likely to have a profound effect on how they master or do not master subsequent stages.

Preventive Intervention Implications
Over the last two decades, there has been a remarkable increase in the quantity and quality of evidence-based preventive interventions for children, youth, parents, and adults. The basic building block for developing effective preventive interventions is a knowledge of human development across the lifespan. The evolving study of adult development provides a rich groundwork in which to consider mounting effective preventive interventions. For example, Phyllis Silverman (1986) has devised an innovative widow-to-widow intervention program based on the understanding of the stages of grief outlined by Kubler-Ross (1969) and the vital role of close social relationships in coping with grief. Rick Price et al. (1992) have developed an innovative job retraining program, initially for workers in Michigan who had lost their jobs, that has shown long-term effects on reemployment and also on mental health dimensions in providing what may be deemed a second chance opportunity in adulthood. These are two examples of effective preventive interventions being built both on an understanding of adult development and on the challenges presented by a particular crisis.

Recent reports have emphasized the need for more evidence-based preventions (Institute of Medicine 1994, National Advisory Mental Health Council 2001). A number of registries of effective preventive interventions across the lifespan have been developed. In the future, one of the most promising areas in the study of adult development will be to link advances to the development of new and effective preventive interventions. In this, it will be particularly important to consider adults in their own developmental trajectories and adults in their roles as parents. There is a consensus across preventive intervention efforts that strength-based approaches are best; hence, the need for understanding healthy development from a nonpathological point of view. There is equally an awareness that family strengthening interventions have great power (Beardslee and Knitzer 2003), which inherently take advantage of the two generational opportunities. Finally, undoubtedly, on multiple levels as our understanding of developmental plasticity evolves, there will be new opportunities for effective preventive interventions across the lifespan of adulthood.

Conclusions: Adult Development—an Ever-Evolving Field
Another major emphasis of this chapter is that the study of adult development is an evolving field. At present, there are various competing ways of thinking about development. Combining knowledge of the inner life with observable behaviors can be effectively organized around the framework of ego psychology. Broad domains for inquiry have been identified that are likely to remain robust in the future. These include the importance of measurement of observable behaviors, the necessity of a stage sequential approach, and awareness of qualities within individuals, such as ego identity, that acquire stability over time but can also evolve.

These are the building blocks that must be incorporated into any reasonable formulation of adulthood. Although development does take place during adulthood, simple cross-sectional approaches will not lead to the uncovering of developmental processes. This is because the time frames in which adult development occur are so large that it is not possible to see them in short periods.

One of the crucial areas for further study in the future is the way adult development proceeds differently within different cultural groups, either within this country or elsewhere. Cross-national comparisons on the influences of living in a particular country on adult development are also important. Finally, the powerful influences of moving from one culture to another, of immigration legal or illegal, of displacement for economic or other factors, need to be much more fully integrated into the study of adult development.

The growing awareness of the profound influences of gender, culture, and historical context are likely to yield
important new insights about the development of adults. Also, as more complete integrative models are developed about pathways to healthy adult development, these will provide vital information for the development of preventive interventions for individuals at risk either because of familial factors or environmental factors such as exposure to violence or poverty, or because of the particular challenges posed by a stage of adult development.

Late-Life Development

Life-Span Theory

Erik Erikson’s epigenetic framework of adult development was a groundbreaking model and, as elaborated in Chapter 7, it still forms the framework for much of the contemporary perspective on lifelong psychological development. Erikson labeled the final task of development as the attainment of integrity, which he defined as “the acceptance of one’s own and only life cycle as something that had to be and that, by necessity, permitted of no substitutions” (Erikson 1963, p. 268). This Zen-like balance between responsibility and acceptance does seem to mark those who age most wisely and peacefully, but it is no easy achievement.

There are several characteristics of the epigenetic framework that highlight the particular difficulties of late-life development. First, the “life cycle” is no cycle at all. A unique task for the elderly is the acceptance of the finitude of life and the inevitability, even proximity of death. Second, none of the preceding stages is resolved completely in one direction or the other; every adult has some elements of mistrust and some degree of shame and doubt. Not only do these partial resolutions accumulate over years, but also the crises most relevant to earlier phases in life never go away completely. Issues of industry and intimacy persist and recur. As a result, the oldest individuals must use partially developed capacities to juggle a range of challenges. Finally, the successful resolution of the Eriksonian stages requires a supportive environment. Trust is not possible for an infant who is not fed; intimacy can only be achieved with the cooperation of a willing and able partner. In late life, the physical and social environment is not particularly friendly. Physical decline, interpersonal isolation, and societal rejection make the achievement of integrity particularly challenging. Yet, the vast majority of elders achieve satisfaction and fulfillment; despair and distress afflict only a minority (Bienenfeld 1990, Hamarat et al. 2002, Vanderhorst and McLaren 2005).

Coping, Defenses, and Adaptation

One of the most consistent findings in investigations of adult development is that personality traits remain stable across the life span. Mentally healthy elders (i.e., the majority) retain a full repertoire of coping resources. What changes with age is the pattern of adaptive mechanisms used (Costa et al. 1987, Hamarat et al. 2002).

In Chapter 7, the maturing profile of defense mechanisms through adulthood is described. In healthy aging, mechanisms such as acting out and denial are progressively abandoned, and defenses such as sublimation, altruism, and humor are increasingly brought to bear (Vaillant 1977). Defense mechanisms, by Vaillant’s description and by their very definition, are mostly unconscious. They frame the perception and meaning of life events and determine their emotional impact; they may further influence a person’s response.

Coping mechanisms refer more specifically to predominantly conscious ways in which individuals react to stressors. Coping mechanisms may be either problem-focused or emotion focused. Problem-focused coping aims to change the stressful situation; it is directed outside the self. Emotion-focused coping changes the meaning and impact of the situation; it is directed internally. When comparing coping profiles across age cohorts, it is usually found that older groups use less escapism and avoidance than younger ones, but equal levels of problem-solving maneuvers. More precisely, however, coping mechanisms are selected in the contest of particular stressors. When a situation cannot be changed, emotion-focused coping is certain to be more effective. In old age, when increasingly many problems are unchangeable, emotion-focused coping is both more widely used than in younger cohorts and correlated with more effective psychological results. Patterns of coping with successful maturity are thus quite compatible with the patterns of mature defenses in healthy aging (Whitty 2003).

One of the stressors of old age is the proximity of death. Elders report that time passes more quickly for them. This perspective shapes the goals of coping and defense. With increasing age, there is less motivation to expand one’s horizons and accumulate broader experiences, and more motivation to derive meaning from what is available. Thus, coping mechanisms shift away from attempts to reverse a shrinking world of contact and toward increasing the depth and meaning of those relationships that are available (Carstensen et al. 2003). Abraham Maslow (1943) described an ascending hierarchy of needs that motivate human beings (Figure 13–1). Once the most basic level is satisfied, one aims for the next level. For most of adulthood, the progression is
from physiological needs to safety, to love, to self-esteem, and then to self-actualization. In late life, however, acceptance of unchangeable physiological realities forces a distortion of the hierarchy. For geriatric medical patients, the progression begins with self-actualization and then progresses to safety, to self-esteem, to love, and only in the end to physiological needs (Majersik 2005).

**Reminiscence**

Among the adaptive tools particular to later years is reminiscence. While more common with increasing years, reminiscence is not universal and does not seem to represent a biologically based drive (Coleman 2005, Webster 1999). Like other adaptive mechanisms, it is employed for particular purposes. Among the purposes that it can serve are as follows:

- boredom reduction
- death preparation
- identity maintenance
- problem solving
- vehicle for conversation
- intimacy maintenance
- old bitterness revival
- teaching and information for those who will follow
  (Webster 1999).

In general, with increasing years reminiscence is used more for intimacy maintenance and less for bitterness revival. This pattern is consistent with the thrust toward increasing the depth and meaning of relationships noted above. The level of death preparation motivating reminiscence is proportional to life satisfaction (Webster 1999). Those who engage in more obsessive styles of reminiscence and focus on bitterness revival and boredom reduction demonstrate much lower levels of life satisfaction (Coleman 2005).

**Cognitive Changes**

Popular media often portray elders as doddering, forgetful, and amusing. There are real changes in cognitive function with age, but they are more complex than the cartoon image of confused Uncle George. In all of the following discussions, it should be noted that within-group differences in cognitive function increase with age and that two normal 80-year-olds may differ from each other more than the average 80-year-old differs from the average 40-year-old (Grégoire 2001).

Aging affects processing, learning, memory, and intelligence. Processing is the translation of stimuli into usable neural signals. Learning is the acquisition of skills and information. Memory is the storage and retrieval of that information. Intelligence is the capacity to manipulate and apply available knowledge (Bienenfeld 1990).

**Processing and Learning**

The most predictable age-related finding in the realm of cognition is a reduction in processing speed (Spar and LaRue 2006). A representative test of processing speed presents pairs of letter sets and asks subjects to indicate whether the two sets are identical. Subjects are scored by the number of correct matches in a fixed time (Wood et al. 2005). Older groups perform much worse than younger ones on such tasks.

Because learning requires the retention of data into a small “compartment” of memory for just a few seconds before further processing, the reduction in processing speed effectively limits the capacity of this store, leading to a cascade of memory deficits downstream. Executive function is defined as the system of control over virtually all other cognitive functions. It includes planning, abstraction, cognitive flexibility, recognizing rules, selecting relevant information, initiating appropriate actions, and inhibiting inappropriate actions. It is typically measured by tools such as card-sorting tests and abstract associations tests. This function declines in late life, but executive losses are directly proportional to processing speed, and not to age (Crawford et al. 2000, Rabbitt and Lowe 2000). Not only pure memory but also a wide variety of functional capacities, including activities of daily living, driving, and mobility, diminish as a function of processing speed (Wood et al. 2005).

Additionally, older individuals are more vulnerable to distraction when trying to learn information than are younger ones. When groups are given items to learn, the difference between learning with and without distractions increases significantly in later life (Grégoire 2001, Spar and LaRue 2006). When randomly selected, groups of older individuals are much less likely to use mnemonic techniques to learn and retain information than are their younger counterparts. This difference may be a cohort effect; that is, people currently in their 80s had less reason to learn and employ such techniques because they had far fewer lists of things to memorize than did cohorts born half a century later. When taught mnemonic techniques, older people improve their scores on memory tests, but not as much as do younger groups taught the same techniques. Older groups tend not to apply the techniques as consistently or correctly as younger ones. Part of this deficit is a further result of diminished processing speed, which impairs the ability to learn and retain the techniques, but part is also due to a reduced ability to adopt the associations required to make the techniques work. The latter limitation is a function of neural plasticity, which is elaborated below (Jones et al. 2006).

**Memory**

Memory is not a singular function, and its parts are variably affected by aging. Immediate (or short-term) memory holds a small amount of information, the size of about seven digits, for a few seconds (Figure 13–2). In general, the capacity of this store is not affected by age, but processing speed and vulnerability to distraction play a significant role in making it less efficient. Working memory allows one to manipulate the data from immediate memory and process...
it for further storage. Its capacity is directly affected by diminished processing speed with increasing years. Working memory encodes data for long-term storage. Because of the learning deficits described above, it declines moderately with age, though its total storage capacity is stable. Remote or long-term memory is more variably affected by aging. Information put into long-term store appears to remain intact, but retrieval mechanisms may become less efficient. New information put into long-term memory is similarly filed less efficiently, making subsequent retrieval unreliable (Craik 2006). Elements of personal history are least vulnerable to long-term memory effects of aging (Spar and LaRue 2006).

Verbal memory consistently declines with age. Spatial memory, as measured by location of pieces on a chessboard or objects on a map or in the real environment, also becomes less effective with age. Pure visual memory, however, as measured by recollection of geometric shapes, appears much less vulnerable (Shaw 2006). Explicit memory, as evidenced in pure verbal recall, is more severely affected by aging than is implicit memory, which drives learned motor tasks (Spar and LaRue 2006).

Intelligence

The most long-accepted model for describing and explaining the effects of aging on intelligence is Horn and Cattell's (1966) model of fluid and crystallized intelligence. Crystallized intelligence is the accumulated body of knowledge about one's world and the skills used to function in it. Fluid intelligence includes the "processes of reasoning in the immediate situation in tasks requiring abstracting, concept formation and attainment, and the perception and education of relations" (Horn and Cattell 1966). When common intelligence instruments, such as the Wechsler Adult Intelligence Scale, are measured grossly against age, the results are inconsistent and unrevealing. When subsets of the scales are separated, verbal scores, which reflect crystallized intelligence, remain stable and even increase modestly. Subsets that require novel thinking and manipulation of knowledge, reflected in performance scores, decline gradually from early adulthood; these functions are representative of fluid intelligence. Since crystallized intelligence is the product of experience, and fluid intelligence depends on neural factors that decline with age, the model is useful and consistent (Bienenfeld 1990, Grégoire 2001). Yet, there are details that require a more nuanced view of intelligence in late life.

Age-related diminution of processing speed, along with increased distractibility, expectably reduces the capacity of working memory. As a result, there is a reduced capacity to hold all the information needed to solve an immediate problem in reasoning. In the face of this effect, inductive reasoning (the ability to draw general conclusions from specific instances) and deductive reasoning (the ability to draw specific conclusions from general rules) decline proportionately and are reflected in measures of fluid intelligence. Reduction of scores on tasks such as digit-symbol substitution depends much more directly on visual processing speed than on pure visual memory (Grégoire 2001). Executive function, which is similarly affected by reduced processing speed, is more significant for the spatial and organizational tasks of fluid intelligence than it is for the verbal and explicit capacities defined in crystallized intelligence (Shaw 2006). In intelligence, even more than in measures of pure memory, within-group variability increases dramatically with increasing age of the cohorts (Grégoire 2001).

Plasticity

The neural substrate of memory and intelligence is affected in many ways by aging. The concept that captures its effects most effectively is the notion of plasticity. Functional imaging of the brain allows investigators to identify the neural correlates of many of the changes described above. When groups of younger and older adults are taught a visual mnemonic technique, younger groups tend to improve more than the older ones. Both positron-emission tomography (PET) and functional magnetic resonance imaging (fMRI) demonstrate that younger people who learn the mnemonics show increased activity in the left dorsolateral prefrontal cortex, while older groups, both those who show improvement and those who do not, fail to display this increase in activity. Activity in the more posterior occipitoparietal area correlated with improved function on this visually intensive technique, in both young and old subjects. Similarly, activity in the medial temporal lobe is associated with associative and paired learning. Mnemonic techniques would have to
use this area to be effective. Older learners whose memory capacity improved with the mnemonics showed enhanced medial temporal activity—less so than younger participants, but much more than older ones who failed to learn the techniques (Jones et al. 2006). In sum, the brain structures that are required for the acquisition of memory-enhancing functions become less able to do so with increasing age, in a pattern that exceeds the effects of reduced processing speed alone.

Many of the declines in cognitive function described above seem to be less dramatic in individuals of higher educational achievement. Common wisdom holds that continued intellectual engagement in late life is somehow protective against loss of memory and intellect. More specifically, higher levels of education are associated with less severe declines in verbal scores on intelligence tests, but measures of fluid intelligence levels of education are associated with less severe declines are lit from behind and to drive at night. Spots and floaters affecting the ability to see faces of people who become less able to do so with increasing age, in a pattern that exceeds the effects of reduced processing speed alone.

Presbyopia

Vision

Presbyopia is the term applied broadly to all age-associated sensory changes with aging is presented in Table 13–1.

Sensory Changes

Just as healthy development depends on a base of sound cognition, so do memory and intelligence require reliable sensory input. Sensation and discrimination are affected by age and put their stamp on many manifestations of mental function. As with cognition, the effects of aging are both more specific and more subtle than the images portrayed by conventional wisdom. A summary of sensory changes with aging is described above seem to be less dramatic in individuals of higher educational achievement. Common wisdom holds that continued intellectual engagement in late life is somehow protective against loss of memory and intellect. More specifically, higher levels of education are associated with less severe declines in verbal scores on intelligence tests, but measures of fluid intelligence levels of education are associated with less severe declines are lit from behind and to drive at night. Spots and floaters affecting the ability to see faces of people who become less able to do so with increasing age, in a pattern that exceeds the effects of reduced processing speed alone.

Functional brain imaging is consistent with the psychometric findings. In tasks of verbal recall, young adults will remember details as well as the essence of a story. Older adults become more likely to omit details but retain the meaning. PET and fMRI show that younger adults tend to localize activity for such tasks, but with increasing age, the cortical representations become more diffuse. This effect may represent either compensation by recruiting or else a dedifferentiation. Dedifferentiation is comparable to the intellectual patterns of younger children who may identify all pets as “doggy” or all vehicles as “car” (Craik 2006).

Vision

Presbyopia is the term applied to aging-related diminution in the flexibility and clarity of the lens. As a result, near vision is compromised and activities such as reading and sewing become more difficult. Additionally, glare becomes a problem, affecting the ability to see faces of people who are lit from behind and to drive at night. Spots and floaters increase with age and, although they are inherently harmless, can be a source of subjective distress. Cataract, glaucoma, and macular degeneration are not normal at any age, but become more common with increasing years and significantly affect functional capacity and mental well-being (Pennsylvania Optometric Association 2006).

Of Americans over age 70, almost one in five is blind in one or both eyes (Crews and Campbell 2004). Many more have significant visual impairment than complete blindness. Vision loss is frustrating and aggravating. It diminishes one’s sense of psychological security and ability to communicate (O’Donnell 2005). Compared with visually intact elders, those with impaired vision report less engagement in leisure activities and social functions, poorer capacity for instrumental activities of daily living (IADL), impaired mobility, and increased levels of medical utilization, hip fractures, mortality, depression, and family stress (Crews and Campbell 2004). In most studies, prevalence of depression in visually impaired elders is about twice the rate in visually intact age cohorts. Loss of valued activities such as reading and driving is discouraging. The effort required to undertake IADL is often sufficient to reduce motivation and functional independence (O’Donnell 2005). And even in the absence of blindness, changes in visual acuity are proportionately reflected in most measures of cognition, including verbal learning, executive function, processing speed, and cognitive flexibility (Valentinij et al. 2005).

Hearing

Presbycusis is the term applied broadly to all age-associated hearing loss. About 40% of Americans over 65 have some hearing loss, compared with 10% across all ages. Some of this loss is due to reduced flexibility in the ossicles that conduct sound, but more is the result of the loss of hair cells in the cochlea. This loss is most extreme in the cells that detect high-frequency sounds, and it gradually progresses to lower frequency cells. Additionally, temporal resolution of sound signals decreases with age, as does “spectral resolution,” the ability to discriminate pitch.

These changes have functional significance. Loss of acuity for high-pitched sounds in speech (such as the voiceless consonants f, k, p, s, t, and ch) makes it hard for people to understand speech; indeed, most complain of difficulty understanding long before they complain of inability to hear. As the frequency spectrum becomes compressed, speech loses some of its musicality and becomes more monotonous; attention may require more effort. Many important signals, such as alarms, turn signals, and gas leaks, are of high frequency and may be inaudible to some elders.

Temporal resolution of sound is the basis for localization, as the brain compares the difference in timing of signals coming from the two ears to determine the source of the sound. As temporal auditory resolution declines with age, so does the capacity for sound localization. This circumstance can be dangerous and can also be frustrating in social environments. Similarly, resolution of sound spectra normally allows one to filter out background noise. Reduction of this capacity with age makes it harder to recognize alarms or discriminate speech in noisy settings (Gates 2005, Wingfield 2005).

Hearing loss is associated with social isolation and depression. Hearing-impaired elders are more susceptible to falls and stroke and demonstrate diminished mobility. They have difficulty sustaining social participation. Further, hearing loss is associated with increased incidence of dementia and accelerated cognitive decline in those who have dementia (Crews and Campbell 2004). The extra effort needed to discriminate and process speech places increased demands on cognitive resources, leaving less available for encoding signals into memory (Wingfield 2005).

Much hearing loss, due to both aging and disease, is correctible. But of all those who could benefit from hearing aids, only 20% ever purchase them; of those, about one in three either abandon or underuse their aids (Gates 2005).

Smell and Taste

Most of what is experienced as “taste” is in fact a combination of signals from taste buds on the tongue and olfactory receptors in the nose. Both types of cells die off with age. On the tongue, salt and bitter taste buds are lost out of proportion to sour and sweet ones, resulting in a change in perceived flavors of particular foods with age (Rawson 2003). Olfactory cells are lost much more severely and smell is affected more than taste by aging (Wysocki 2006). In addition to cell loss, there are age-related changes in receptor proteins and ion channels. The presence of dentures and adhesives alters taste and smell. Reductions in these acuities are noted early in Alzheimer and Parkinson diseases, which are age-related illnesses.

Not only does the sense of smell become generally diminished, but there is a reduced ability to discriminate smells, as this sense is more crudely tuned to specific aromas. A significant functional effect of these changes is that food loses some of its appeal and selection of foods becomes less varied. Nutritional balance may become compromised (Rawson 2003).

Touch

The threshold for tactile sensation rises dramatically with age. The ability to distinguish separate touches, measured by the minimum distance necessary to discriminate, weakens with age. Both of these effects are more marked peripherally than centrally (e.g., more in the finger than on the abdomen). As a corollary, hand strength drops, as do pinch force and precision. Functionally, the result is poorer capacity and increased effort required for fine movements, such as buttoning and eating (Ranganathan et al. 2001, Stevens et al. 2003).

Lifestyle

Physical and psychological changes outlined so far do not all occur as inevitable consequences of aging. Personal choices and behaviors can have a substantive influence. Smoking is an obvious example. It accelerates many age-related physical changes, and resulting smoking-related illness and disability contribute to a vulnerability to depression and reduction in perceived quality of life. By aggravating vascular deterioration, it increases susceptibility to cerebrovascular disorders and is associated with higher rates of both vascular and Alzheimer dementias. Cessation of smoking yields benefits at all ages, including senescence (Flicker et al. 2006, Taylor et al. 2004).

Diet

Age brings undesirable changes in metabolism, with detrimental effects on cognition and mood. The prevalence of diabetes increases with age and usually comes in the context of the metabolic syndrome (including obesity, hypercholesterolemia, and hypertension). Diffusion of glucose through the extracellular fluid diminishes and with it the delivery of the brain's sole source of energy. With elevated glucose levels, more proteins become glycosylated, negatively affecting signal transduction in the brain. The metabolic syndrome is accompanied by more reactive oxygen species, leading to diffuse neural damage. In the presence of insulin resistance, there are elevated levels of both glucose and insulin, leading to inflammatory damage to brain cells and vasculature. Further, insulin normally plays a positive role in memory, synaptic transmission, neurogenesis, and the clearing of beta-amyloid, a pathogenic protein involved in Alzheimer disease. The relative weakness of these effects in insulin resistance, and in later stages of diabetes where absolute insulin levels drop, contributes to further brain vulnerability.

Impaired glycemic control is most directly associated with explicit and episodic memory, as well as other functions of the hippocampus and nearby structures. Individuals with Type II diabetes are more susceptible to Alzheimer disease. Diabetes at all ages is correlated with disproportionate rates of depression (Hendrickx et al. 2005).

All these negative metabolic effects can be slowed with lifestyle changes. Proper choice of diet, pharmacologic control of diabetes, and exercise can have salutary effects. Diets low in high-glycemic-index carbohydrates positively affect glucose levels and the risk of metabolic syndrome. Avoidance of saturated fats can also help reduce the risk of cerebrovascular deterioration. Oral hypoglycemics may stabilize memory function early in Alzheimer dementia (Hendrickx et al. 2005).

The role of specific nutrients is less clear. Reductions in dietary homocysteine and vitamin B12 are common in old age and associated with impaired cognition. However, poor cognition may lead to poor food choices, which are then reflected in lower levels of homocysteine and vitamin B12. Evidence that omega-3 fatty acids may retard cognitive and physical deterioration is inconclusive. Supplementation antioxidants such as vitamin E are popular, but their efficacy in affecting mental or physical changes is unproven (Flicker et al. 2006).
Exercise

The Centers for Disease Control and Prevention (CDC) has outlined minimal recommendations for physical activity by older adults, stipulating they engage in at least 30 minutes of moderately intense physical activity at least 5 days and preferably 7 days per week. These exercise sessions should include both cardiorespiratory and strength programs (Centers for Disease Control and Prevention 2006). Exercise of moderate intensity is the equivalent of at least brisk walking. However, this goal is rarely achieved. Overall, fewer than one in ten persons over age 64 meet the CDC recommendations. Fully two thirds of persons in this age group, and 90% of those age 85 or older, are “inactive,” which is defined as performing less than one 30-minute episode per week (Taylor et al. 2004).

Lack of exercise contributes to the metabolic problems described above (Hendrickx et al. 2005). Muscle weakness is directly reflected in the frequency of falls, which often precipitate a cycle of functional, cognitive, and affective decline. Osteopenia increases the risk of fracture with resulting immobility and dependency.

The capacity to engage in physical activity is not inherently affected by aging, and the benefits are significant. Physical activity improves endothelial relaxation, compensating for some of the effects of age on cerebrovascular function. Resistance training in particular improves strength, flexibility, reaction time, and bone density, with a reduction in the incidence of falls and fractures (Taylor et al. 2004).

More directly, people who exercise the most are the least susceptible to depression (even in studies that negate the effect that exercise reduces depression). In those who are already depressed, physical exercise achieves measurable antidepressant effect. In persons with cardiac and pulmonary disease, it reduces levels of anxiety. The subjective sense of psychological well-being is also strongly correlated with physical activity.

Physical (especially aerobic) fitness is associated with improved performance of executive tests of cognitive function, and rates of cognitive decline vary inversely with the intensity of routine exercise. Individuals with high levels of physical activity suffer reduced risk of dementia in general and Alzheimer disease in specific (Flicker et al. 2006, Taylor et al. 2004).

Sexuality

Physical changes in the reproductive system are numerous and significant, but their effects on sexual function and satisfaction are much less profound than is popularly imagined. Most adults retain a high degree of interest in sex regardless of age and, in the absence of prohibitive illness, achieve considerable satisfaction.

In healthy men, levels of testosterone do not decline measurably even in late life, and levels of sexual desire at age 70 are as much as 90% as high as they are in younger years. However, there is some attenuation of elements of sexual function. With age, men experience fewer morning erections. Their penile sensitivity declines, and they are less likely to achieve erection without direct physical stimulation. Erections may be less firm, and full rigidity may only be achieved seconds before ejaculation.

Further, a number of age-related illnesses can affect sexual abilities in old age. Hypertension and diabetes are leading causes of erectile dysfunction (ED); half of older diabetic men experience ED. The same vascular pathology underlying coronary artery disease is often manifest in penile vascular disease. Many medications prescribed to elders can inhibit desire and function, most particularly serotonergic antidepressants and dopamine-blocking antipsychotics.

Yet, overall, of men over age 70, more than 75% engage in sex at least once a month, and one third do so at least weekly. The best predictors of a man’s level of sexual activity and satisfaction in old age are his own health, his level of sexual function in younger years, and the health and interest of his partner (Metz and Miner 1998).

In women, the loss of estrogen is responsible for most physical changes. The vaginal epithelium flattens, becoming more vulnerable to bacterial infection and vaginitis. There is atrophy of the labia majora, a loss of fat and subcutaneous tissue from the mons pubis, a reduction in vaginal secretions and a loss of elasticity in the vaginal barrel. All these changes can make vaginal intercourse uncomfortable. Functionally, the excitement phase takes longer to achieve and the plateau phase of the sexual response cycle is prolonged. Capacity for orgasm is retained, although the number and intensity of vaginal contractions is reduced (Table 13–2).

Medical conditions such as arthritis and hemorrhoids, along with surgical procedures to the hips and abdomen, may be causes of dyspareunia. As in men, medications including especially antidepressants and antipsychotics can affect desire and function (Gelfand 2000). The loss of reproductive capacity at menopause may cause some women to see themselves as less desirable and secondarily reduce their own levels of sexual desire. Similarly, those who perceive graying hair and aging skin as unattractive may stop seeing themselves as sexual beings (Kingsberg 2000).

Because women outlive men, there are fewer unattached men than single women among the elderly, and this cohort tends to engage in sex only as part of a stable relationship. As a result, men engage in much more sexual activity in their later years than do women. Nonetheless, diminished levels of activity in both sexes are not accompanied by any loss of enjoyment.
Older people find ways other than vaginal intercourse to achieve sexual satisfaction, including masturbation, cuddling, and fondling. Negative attitudes about sex learned in younger years may impair one’s ability to enjoy sex later. In general, the level of sexual activity in late life is directly proportional to the levels achieved at younger ages. Age-related changes in sexual activity are more in the realm of types of activities than in amount, interest, or enjoyment (Deacon et al. 1995).

Ancient Times
As human beings we are inescapably social animals, dependent on the group for our welfare and survival. Perhaps unique among species, we are also aware that our lives are of finite duration. This double consciousness—of our interrelatedness and our ultimate death—shapes our behavior and our personalities. Since prehistoric times, the bulk of persons within the human community have noticed that some fraction of their number behave or think or show emotion in ways that differ markedly from the rest of the group—ways that are odd or maladaptive or, in extreme cases, dangerous to the welfare of the persons themselves or to the group at large. It was this fraction that became the domain of the early “healers of the mind”—most of whom, in this long era far distant in time from the days of organized medicine, were wise elders or religious adepts. Their collective wisdom and recommendations to those who were of “troubled soul” constitute the forerunners of psychiatry, whose Greek roots convey this very notion: healing the soul.

Long before the age of reliable psychodiagnosis (at most, the past 200 years of our million-year history), a primitive vocabulary developed to label the odd and disturbing people within the body social: terms like wild or eccentric or mad. The first word in Homer’s Iliad—مانیس or “wrath”—is the origin of our word mania; Homer used it to describe the overpowering rage of Achilles when he felt that he was cheated of his “prize” (the captive girl Briseis). In time, people who were wild, eccentric, or mad were called insane (whose Latin roots convey merely “not healthy”), especially if their behavior was so aberrant as to make living within their own families intolerable.

It is impossible to pinpoint a date for the first example of a psychotherapeutic intervention by some wise person (within or outside the realm of religion). Suffice it to say that this primordial intervention, whatever form it took, must have antedated by many thousands of years the example I am about to relate, which occurred 2,500 years ago, or about 2 millennia before we can speak of anything like organized psychiatry. This story has become part of standard Buddhist teachings and, although cast in the form of a parable, seems to reflect an actual event in the life of the Buddha, between the 5th and 6th centuries bc:

The young wife of a wealthy family, Kisagohtami by name, suffered the death of her only son, and in the aftermath, lost her mind. She would grasp his cold body in her arms and go about wandering in the streets, asking here and there whether there were someone who could restore her “sick” child. The townspeople, having no idea what to do for this crazed soul, would gaze sorrowfully at her and walk on past. However, a devotee of the Buddha, who could not help noticing the woman as she walked nearby, suggested to Kisagohtami that she go with her child to the abode of the Buddha in Gionshohja. Straightaway, the woman took herself to the Buddha, carrying the child in her arms. The Buddha, calmly surveying her situation, said to her: “Woman, to restore this child it will require seeds of the poppy. Go then into the town and obtain four or five grains of poppy. These poppy seeds must come from the house of only such persons who have never been touched by Death.” So the crazed mother went out into the town asking for poppy seeds. The seeds themselves were easy to find—though not from the house of someone whom Death had never touched, for there were no such houses. At last, unable to obtain the seeds from such a house, she returned to the abode of the Buddha. There, in the company of his calm figure, she began to realize the inner meaning of the Buddha’s words. As though awakening from a dream, her mind was restored, and she buried the cold body of the child in a grave. After she did this, she returned to the abode of the Buddha and became his disciple. (Source: Bukkanoh Seiten, pp 186–188; my translation from Japanese.)

What is remarkable about this example is the extraordinary sensitivity of the “therapist” (here, Siddhartha...
Gautama, who became the Buddha, the Enlightened One)—not only to the plight of his distraught “patient” in her “brief psychotic episode” after the death of her infant, but as shown by his instantly finding a way to help her save face. Rather than shaming her by pointing out the obvious, the Buddha gave her an exercise, whose completion was most likely to be accompanied by satori, enlightenment (today we would speak of it as insight). Out of his wisdom and compassion he devised a gentle trickery by which she, in effect, cured herself.

In speaking of the soul, our ancestors often divided the concept into various compartments: the intellect, the emotions, the perceptions, and the passions. The soul was in the hands of the Gods; its explication, a matter for priests and philosophers. For the ancient Hindus and Egyptians and Israelites alike, madness, as a derangement of the soul, was a manifestation of the divine or “possessed.” Persons we might consider psychotic were often thought to be possessed by demons (“evil spirits”). In about 1000 BC, as an example, King Saul had grown envious of David after David’s reputation had outstripped his after he killed Goliath. Saul tried to kill David (1 Samuel 18:11), an urge described as having arisen out of the “evil spirit which came upon Saul.” Later, when his army was defeated by the Philistines, Saul committed suicide. A little earlier, David feigned madness when captured by the forces of the Gath king Achish, who, because he would not kill an insane man, promptly released David. Elsewhere, we encounter Hannah, the mother of King Samuel; she was for years depressed, tearful, and bitter because she was unable to conceive. When she eventually did, she became arrogant and grandiose. The prophets Jeremiah and Ezekiel were both fanatical social critics and prophets. Jeremiah and Ezekiel committed suicide. A little earlier, David feigned madness when captured by the forces of the Gath king Achish, who, because he would not kill an insane man, promptly released David. Elsewhere, we encounter Hannah, the mother of King Samuel; she was for years depressed, tearful, and bitter because she was unable to conceive. When she eventually did, she became arrogant and grandiose. The prophets Jeremiah and Ezekiel were both fanatical social critics and truthayers. Ezekiel went so far as to follow God’s command (as he heard it) to eat bread made with “dung that cometh out of man” in sight of the Israelites, whom God had wanted to humiliate for their sins. What can we say of these Biblical figures? Was Saul manic–depressive? Was Hannah dysthymic? Were Jeremiah and Ezekiel paranoid? We do not know enough about their personal histories or about the culture of their time and place to situate them confidently within this or that category of our diagnostic manual. Certainly in a culture in which it is normal to hear God’s voice, this does not constitute a hallucination. All these figures stood out from the average enough to have the biblical authors give us these few details about their emotional life. Which were supernormal, which like our schizophrenics, which had mild personality disturbances or “neuroses,” we cannot say.

**Beginnings of a Methodological Approach to Mental Phenomena**

In Hinduism and its 6th-century offshoot, Buddhism, mind and body were not conceptually separate. Mind was seen as an aggregate of causes and conditions, something composed of atoms that come together for a time, destined to fly apart later on and insert themselves in other objects or creatures. This atomistic view is also noted in the works of certain Greek philosophers, such as Eratosthenes: it does not lend itself to a theory of mind built on notions of stability, let alone compartmentalization into categories of normal and abnormal types. About 500 BC, before the era of Hippocrates, the Hindu physician Sushruta began to picture mental illness as something distinct from possession by demons; he thought that the causative factors were strong emotions and passions.

Plato (427–347 BC) embraced a dualistic theory in which mind and matter were separable. “Mind” overlapped conceptually with “soul” and was divided into a rational soul (immortal, divine, and located in the brain) and an irrational soul (in the chest, near the heart, the seat of anger, and the abdomen, the seat of the “lower passions”). The forms of “madness” consisted of melancholia, mania, and dementia, which occurred when the irrational soul became decoupled from the rational—something that happened when there was a maldistribution of the chymoi or humors that reached the irrational soul.

Plato’s pupil Aristotle (384–322 BC) viewed the brain’s function as one of condensing vapors that emanated from the heart. This notion still held sway in the 18th century, when alienists (as mental specialists were then called) like Purcell and Pommé spoke of the vapors as responsible for nervous states, especially hysteria.

Aristotle’s pupil Theophrastus (370–285 BC) developed a rudimentary characterology in which he gave brief sketches of some 30 traits. Many of these read like the “items” of our current personality disorders as described in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM). Theophrastus’ characters included, for example, memphisomnia (“querulousness”) and apisitia (“distrustfulness”), elements of what we would call paranoid personality.

Hippocrates (460–377 BC), a contemporary of Plato and, unlike the aforementioned philosophers, a physician, was primarily a systematician. His theories were oriented toward anatomy, physiology, and temperament. Variations in the four humors—earth, air, fire, and water—were held accountable for fears, shame, grief, and other mental states, including positive ones like pleasure. Phlegm was equated with the water element; the froth that accumulates during a grand mal seizure Hippocrates took as evidence for “excess phlegm.” In this, as in other mental conditions, he ignored the nerves in favor of the blood vessels. Based on what he saw of the body’s remarkable recuperative powers, Hippocrates’ prescription for treatment relied heavily on the idea of giving nature a chance, that is, not interfering with the body’s ability to heal itself. As for the frenzied state called hysteria, Hippocrates endorsed the then prevailing notion that hysteria affected only women and that it resulted from the womb (Greek hystera) traveling periodically to the brain. His recommended cure was the same as Pinel’s in the 1790s: early marriage (suggesting that ancient as well as early modern physicians saw a connection between hysteria and sexual frustration).

The philosopher Epicurus (342–270 BC) spoke of both rational and irrational emotions, recognizing that in many instances fear, grief, or anger might be justified by circumstances and thus “rational.” Epicurus and his followers represent a humanistic attitude, emphasizing the individual, in contrast to the biological orientation of Hippocrates, a distinction we see repeated over and over in the ensuing centuries. The Epicurean school preferred “moderate discourse” in persuading patients to change their irrational ideas, although sometimes it was recognized that more outspoken language was required to divert a patient from some destructive path.
At the beginning of the Common Era we find what is arguably the first example of self-mutilation: in the New Testament there is mention (Mark 5: i–xi) of a hermit “possessed of an unclean spirit” who was always “crying and cutting himself with stones.” Jesus cured the man by ordering the evil spirit to depart from him, here continuing the Old Testament tradition of picturing mental aberration as a matter of good versus evil, related to the world of spirits rather than to the realm of medicine.

At the end of the 1st century AD Artemidorus of Ephesus compiled a Dream Book, outlining some 130 common dream symbols (e.g., hair, teeth, ants) and their alleged meaning. This approach remained the popularly accepted way of understanding dreams until Freud’s Traumdeutung in 1899.

Roman, Greek, and Other Influences in Early Christian Times

The Roman encyclopedist Celsus, a contemporary of Christ, accepted humoral theory, adding that the humors flowed more freely during springtime—hence the frequency, as he viewed it, of melancholia and insanity during this season. His recommendations for treatment varied from mild to harsh: melancholy might be relieved by soft music, yet in cases of visions, of either the depressed or hilarious (manic) type: Celsus thought that the best approach was “torture, starvation, fetters, or flogging” (methods that hardly fell out of favor over the next 1,800 years).

A generation later, Aretaeus of Cappadocia expressed the opinion that melancholia and mania were different forms of the same malady, a modern conception reminiscent of Falret and Baillarger (folie circulaire, folie à double forme) in the 1850s. He favored descriptive trait words over “humoral” language, speaking of certain persons as “irritable, violent, and given to joy” rather than simply “manic.”

The standard Roman nosology consisted mostly of Latinized terms from the Greek: 

- Phlegmatic
- Choleric
- Sanguine or manic
- Melancholic

The standard Roman nosology consisted mostly of Latinized terms from the Greek: *furius* (for mania), *vesania* (similar to paranoia), *amentia* (for those born without good intellectual function), *dementia* (for those who lost intellectual function later), and *stultitia* (for idiocy). Melancholia was retained without Latinization.

Bulimia was recognized as a mental condition around this time; it is mentioned in the Talmud as a valid excuse for eating during the holy fast day of Yom Kippur. The word *vesania* (similar to paranoia) was also used by the rabbis. The term *vesania* meant “suffocation” or “suffocation” of the womb, rather than to its traveling to the brain.

Post-Roman and Medieval Times

The millennium from the fall of Rome in the 5th century spans the so-called Dark Ages and the medieval period. Galen’s teachings were kept alive via transmission to Persia, then to the court of Harun al-Rashid in Baghdad. Greek medical learning reentered Europe in the 11th century, thanks to translations of a compendium by the Arabic physician Avicenna.

The philosophy of the early Christian church was in part a reaction against the anarchic sexuality and corruption of the Greco-Roman world. The early Christians took pride in sexual abstinence and in sparseness of diet, signs of self-denial, and a higher morality. Gradually, faith became more important than logic; mental abnormalities were once again understood mainly as manifestations of evil and deviltry. Belief in evil spirits, ghosts, incubi, and succubi (female versions of incubi) replaced reliance on science and observation. Sexual repression, particularly intense among the celibate clergy and nuns, sometimes exploded into “hysteric” crises, taking such forms as bouts of fasting, showing the stigmata, self-mortification, or chaotic behavior.

In areas of Europe where the Moors made their conquests, however, the rational and humane treatment of the mentally ill championed by the Greeks was now introduced by Arabic physicians and scholars. Ibn-Rhazes (860–930), for example, kept a separate wing in his hospital for the care of the insane. Similar humane institutions were established in Moorish Spain. A contemporary of Rhazes, Unahlmad, developed a classification that included, besides melancholia and mania, delirium, persecutory psychosis (*kutrib*), and lovesickness (*ishk*).

The neoplatonist Avicenna (980–1037) was both an encyclopedist of medicine and a master clinician. He once diagnosed depression related to lovesickness in the nephew of the king in Avicenna’s native Persia: by feeling a quickening of the young man’s pulse as a townsman recited in the doctor’s presence the various quarters and streets and houses in the city, Avicenna was able to demonstrate that the man was pining for a woman. He brought a woman from such-and-such a house on a certain street. Although deeply mortified, the man admitted Avicenna was correct. The king, on hearing of the doctor’s finding, quickly approved the marriage (the woman, although related, was only a cousin), and the man’s depression at once lifted.

In the Arabic world, many of the common people still believed in spirits, called *jinns* (the origin of our genie), who were blamed for provoking mental disturbances. Arabic
scholars, such as Avenzoar and Averroes of the 12th century, rejected this notion, although their rejection had to be worded delicately so as not to offend the populace. The Jewish physicians and moralists of this age were less at the mercy of these superstitions. Maimonides (1135–1204), born in Spain, spent most of his life at Saladin's court in Cairo, where he wrote extensively on the soul, on his Guide to the Perplexed, and on ideal behavior. For the last he relied heavily on Aristotelian conceptions of the golden mean: good deeds, for example, are those that are equilibrated, maintaining the mean between two bad extremes—the too much and the too little.

In 13th-century Spain there were groups of Christian and Jewish mystics in touch with one another, each influencing the other. A figure of importance, albeit indirect, for psychiatry was Avraham Abulafia of Saragossa, who spent most of his life at Saladin's court in Cairo, where he wrote extensively on the soul, on his Guide to the Perplexed, and on ideal behavior. For the last he relied heavily on Aristotelian conceptions of the golden mean: good deeds, for example, are those that are equilibrated, maintaining the mean between two bad extremes—the too much and the too little.

What may be understood as the origins of community psychiatry took place around this time in the small town of Gheel in Belgium. It was there that an Irish princess repaired, so the legend has it, after her flight (during the 7th century) from the incestuous advances of her father. Saint Nymphna, as she became known, took holy orders and cured several persons of “demonic possession.” A 12th-century church was built in Gheel honoring her and became a refuge for the insane. In recent centuries, the townspeople have taken in as boarders chronic mental patients who are well enough to sustain extramural life. Esquirol, who visited Gheel in 1822, held up the town and its people as a model of humane concern for the mentally ill, a reputation it enjoys to this day.

Many examples of “fasting girls” became well known in the 13th century, including Princess Margit of Hungary (for whom Budapest’s Margitsziget, Isle of Margaret, is named), and the Venerable Lukardis, the German nun who became the first to show the stigmata. The Church eventually discouraged this kind of self-mortification, although the tendency toward anorexia nervosa, especially in adolescent women, has persisted in the West, reflecting similar “dynamics” related to fears about adult sexuality.

The 13th century also witnessed the struggle between the reactionary inclinations of the Church and the burgeoning rational and scientific spirit of the professors, whose number and influence were on the rise, owing to the construction of many universities throughout Europe. Progress toward a more rational view of the mentally ill was severely impaired for many decades after the Great Plague of 1347–1348, when Europe lost a third of its population. Not understanding the cause of the disaster, a rat-borne bacillus, people blamed the Devil, the Jews, or their own “sinfulness” (the flagellants of Hungary exemplifying the last). Also blamed were the one group of creatures whose efforts could have slowed down the Plague, cats, many of whom were caught and destroyed as though they were the embodiments of the Devil. More important, many women were also singled out as witches, held responsible through their supposedly wicked dealings for the ever-mounting death toll. Yet even in this dark time a few forward steps were made in the care of the insane: the first asylum in Europe was built in Hamburg (1375), followed by others in Valencia (1410) and in London (the Bethlehem Hospital, known then and now as “Bedlam,” from which the popular word for chaos derives).

The confrontation between dogmatism and scholarship continued during the tumultuous 15th century. The conquest of Constantinople by Mehmet II in 1453 led to a flight of Christian scholars westward, bringing with them Greek and Latin learning and helping to usher in the Renaissance. Meantime the widespread sale of indulgences by the Western Church, to defray the expenses of the Crusades (beginning in the 11th century), alienated many of the faithful and became one of the root causes of the Protestant Reformation. The continued witch hunting and preoccupation with heresy, especially in the Spanish court of Ferdinand and Isabella, led to persecution of the new Christians (the conversos who had converted from Judaism after the persecutions of 1391 and who were now fully assimilated Christians). Pope Innocent VIII empowered his Inquisitors to punish those who strayed from the true belief; 3 years later in 1487 the Dominican monks Kraemer and Sprenger published their guidebook for the Inquisition, the Witches’ Hammer, asserting that “all wickedness is but little to the wickedness of a woman.” Ferdinand and Isabella gave the Inquisition a free hand in persecuting those whom it deemed heretics: witches, Moors, Jews, and new Christians (false accused of “Judaizing”) alike. The importance to psychiatry of these events was significant. Because of the expulsion, extermination, and denigration of these groups, psychiatry practitioners and those who embodied the scientific spirit fled southwest Europe and headed for more tolerant, usually Protestant-dominated areas. The history of psychiatry from the 16th century until recent times became recentered in Germany, Switzerland, Great Britain, France, and the Low Countries.

16th Century: The Beginnings of Modern Psychiatry

The year 1492 marks a kind of turning point in history. In this year, some 40 years after Gutenberg’s printing press, Ferdinand expelled the Moors from Spain and Columbus discovered America; it was also the birth year of the converso scholar Juan Luis Vives, whom many consider the founder of modern psychiatry.

In his greatest work, De Anima et Vita of 1538, Vives demystified the concept of soul, stating simply that the soul is itself the author and moving force behind our functions, drawing its energy from no divine or external source, only from within the body. He spoke of its various compartments, the five senses, and its capacities: intelligence, memory, recall, talent, thought, and will. These capacities are echoed centuries later in Heinz Hartmann’s notion of the conflict-free ego sphere in his psychoanalytic treatise of 1950. Vives also described the positive and negative emotions: pleasure, sympathy, and joy versus anger, hatred, envy, shame, and arrogance. Vives also championed the idea of his predecessor, Pico della Mirandola (1463–1494), that humans are not mere puppets on the strings of God but have free will and can determine (and are responsible for) their own fate and their own ideals, which can be realized only through education. Vives’ monistic concepts—soul as abstraction of what the brain does (the issue of what it is, if anything, he left to religion)—prefigure the objections to dualism raised by the
early biological psychiatrists such as Griesinger in the 19th century, marking Vives as quite modern.

The Swiss physician Paracelsus (1493–1541) was an outspoken opponent of the witch burners and also denounced Galen and Avicenna as hopelessly old-fashioned. Paracelsus saw mind and body as inseparably intertwined and was one of the first to employ the concept of an unconscious (in relation to people’s often being unaware of the motives behind their behavior).

Even more of a maverick and polymath was Paracelsus’ contemporary, the Milanese physician Cardanus. In line with the then popular pseudoscience of physiognomy, he published a book purporting to diagnose all different character types according to the lines of the forehead (metoposcopy).

The most outstanding physician of the second half of the 16th century, in relation to psychiatry, was the Dutch-born Johann Weyer. A careful observer and thoroughgoing rationalist, he debunked the Witches’ Hammer in his magnum opus De Praestigiis Daemonum (The Deceptions of the Devil 1564). Later he wrote a tract on the “disease of anger,” calling anger the “most fertile mother of numberless evils, converting the nature of man into that of a savage beast.” He also debunked a case of “prolonged fasting” in a young girl by inviting her to his home, where her actions could be closely watched. When she thought no one was looking, she stole food and beer from the pantry, thus establishing herself as a case of factitious anorexia.

To ward the end of the century, Rudolf Goethe, in a treatise on how to improve humankind, used the term psychology for the first time. In Spain, Juan Huarte y Navarro wrote of his theory of what we would call psychology; how to improve humankind, used the term psychology for the first time. In Spain, Juan Huarte y Navarro wrote of his theory of what we would call psychology; how to improve humankind, used the term psychology for the first time.

Physiognomy (diagnosis by the shape of the head), which we can take as the forerunner of biological psychiatry had another ardent exponent Giovanni della Porta (1545–1615), who asserted that a man whose face resembles that of a lion has a “leonine” (brave, fearless) personality; those who look like goats are sexually lubricious, and so on.

One of the first premodern classifiers of mental illness was the Swiss Felix Plater (1536–1614); he used the term alienation, which became the norm for the next 200 years. He ascribed mental disease to brain damage, especially if the brain was “excessively dry”—an allusion to the still widely accepted humoral theory. Treatment was also dictated by this theory; Plater recommended the use of purgatives, as though these would rid the body of an excess of the offending humor (black bile).

Apropos the “black bile” of melancholy, the book on this subject by England’s Timothy Bright (1551–1615) is noteworthy for having influenced Shakespeare (who made many references to melancholia but none to mania) (Bright 1613).

17th Century: Slow Progress in Description and Empiricism

Although the humoral terms persisted (as they do to this day), progress in anatomy (e.g., the dissections of Vesalius) led to further weakening of Galenic notions. Rationalism and empiricism gained ground, albeit slowly. Syphilis was introduced into Europe around 1500, and cases of general paresis were noted increasingly, although the underlying cause remained obscure until late in the 19th century.

In France, Charles LePois (1565–1633) not only disclaimed any connection between hysteria and the uterus but also stated that men could develop hysteria as well, a point that was not well received when Freud said as much 250 years later.

Writing on lovesickness, Jacques Ferrand also fought against tradition, asserting that the heart was not the organ of love; rather, the trouble results from the derangement of the brain, where the imagination has become depraved. Melancholy in this case had nothing to do with black bile but (as with Avicenna’s young patient) with unrequited love.

Philosophers and physicians were at pains to enumerate and categorize the emotions in a rational way. Expanding on Plato’s observation that lust is the most powerful passion, the French theologian Senault created a catalog of 11 passions including love, hatred, desire, despair, anger, and hope.

François Bayle contributed to the understanding of “supposed” witchery and hysteria, drawing attention to the phenomenon of contagion, to explain how a susceptible person near a hysterical person may also become hysterical.

The most important figure in 17th-century French psychiatry was not a physician but the deductive-rationalist philosopher René Descartes (1596–1650). Separating the basic from the complex passions, Descartes (1650) identified six that were irreducible: admiration (in the sense of noticing with surprise), love, hate, sorrow, joy, and desire. A complex emotion like jealousy was composed of desire (for the love object), sorrow (at the loss of this person), and hate (toward the rival). Descartes reasoned that, because it had no bilateral representation and was solitary, the pineal gland must be the center of the soul. In Cartesian dualism, soul and body were of different natures. This argument was to go through many forms over the next 3 centuries, and continues currently as controversies about the relationship of mind to brain.

In Germany, Johann-Caspar Westphal wrote on the immense power of the imagination, which he thought was sufficient to account for the phenomenon of witchcraft, hitherto ascribed to the Devil.

The first English physician to write of women accused of witchery as unfortunate persons suffering from some medical condition was Edward Jorden, whose book (1603) spoke of hysterical “fits” that might occur with remarkable regularity: monthly, yearly, or weekly.

Another case of factitious illness, similar to Weyer’s, was described by Richard Baddley (1586–1670), that of a boy whom Baddley eventually spotted mixing ink with his urine by way of simulating disease. Meantime, Richard Sibbs, a Cambridge theologian, wrote in 1636 about inner conflict, in a manner reminiscent of later psychoanalytic theory: persons who felt tormented between the desire to do what is socially acceptable and the desire to do what is wrong.

The most widely known English book of the 17th century relevant to psychiatry also comes from a theologian, the dean of divinity at Oxford, Richard Burton, whose Anatomy of Melancholy was published in 1621. Interspersed with the encyclopedic references to every aspect of melancholy is a running commentary on Burton’s own case of this affliction (the chief features of which were an inordinate sense of wrongdoing and guilt, despite the exemplary, blameless life.
that the scholar actually led). For treatment, Burton advocated a form of psychotherapy consisting of revealing one’s troubles to a trusted friend. In addition, healthy diet, vacations in the country, and various medications (e.g., aloe, hellebore) were deemed effective.

One of 17th-century England’s most prominent physicians was Thomas Sydenham (of the eponymous chorea). Like most physicians of his age in Christian Europe, he wrote in Latin and on all medical topics, not just those related to the mind. For apart from the few who worked in asylums, there were as yet none who devoted themselves solely to psychiatry. Sydenham used the term hysteria to connote severe mental disorders in general and thought that there was a similarity between hysteria and hypochondriasis (both of which he believed arose from “irregular motions of the animal spirits”).

The great Thomas Willis (1621–1675), of the brain vasculature’s circle of Willis, originated the term neurology and also spoke of the study of the corporeal soul as psychology. A founder of biological psychiatry, Willis implicated the nerves, not the blood vessels, as the realm of simply lesser severity than an epileptic convulsion. Like LePois, Willis was aware that hysteria could be found “in women of all ages and classes, and even in men.” In contrast to Burton’s mild measures, Willis recommended, when faced with “madness,” restraints, beatings, bloodlettings, and other harsh treatments. In his 1672 treatise De Anima Brutorum, we find what is probably one of the earliest descriptions of schizophrenia: adolescents who, although once clever and graceful, become dull, foolish, and insipid; although once intelligent and quick to learn, become enfeebled and listless. This resembles our negative signs; Willis made no mention of the positive signs, like delusions, but we must remember that the clinical picture of an illness such as schizophrenia is culture dependent and is described differently, depending on the era, in accordance with what physicians of the time noticed or thought was important.

Cartesian dualism and the human-as-machine model had many opponents; among them was Lord Chief Justice Matthew Hale, who argued (in 1677) that human perception, memory, and fantasy cannot be reduced to “modification of matter or the natural motion thereof.” He believed in the influence of the moon on mental states (the term lunacy derives from this view) and thus was a forerunner of Richard Mead (18th century). He also put forward the notion of temporary insanity, noting that certain women denounced as witches were “at the height of their distemper at the full moon.” The justifiability of the concept is still being debated in our day and is related to the equally controversial issue of diminished capacity.

Besides the feigned fasting of Weyer’s case, there were true cases as well. Richard Morton (1637–1698), physician to King James II, has credit for the earliest description (in an 18-year-old girl with wasting, amenorrhea, and hyperactivity), which he called a consumptive disorder. The term anorexia nervosa was not coined until William Gull’s treatise in the 1860s.

Despite the ascendancy of rationalism and empiricism in England, belief in magic and the miraculous hardly disappeared. Effecting cures of various diseases by the queen’s touch or by the laying on of hands was widely practiced. Outstanding in this regard was Valentine Greatraks (1628–1683), a devout Protestant soldier in Oliver Cromwell’s army. In 1649 he began to feel himself possessed of the benevolent power to cure others by his touch. Patients flocked to him by the hundreds, mostly with palsies and headaches, but others with “possession,” hysteria, and other mental disorders. Greatraks’ touch depended for its efficacy on his faith in himself and on his patients’ faith in him, which constitute a testimonial to the powers of suggestion, faith, hope, and the body’s natural self-healing tendencies. Both reason and imagination, sound medical tradition but also faith, have their place. A healer like Greatraks reminds us that medicine, in its effort to be wholly scientific, cannot afford to shun the humanistic and the mysterious.

The themes of reason and imagination are clearly intertwined in the great treatise of Francis Bacon (1561–1626), The Advancement and Proficiency of Learning (1640). Through his encouragement of physiological experiment and careful description, Bacon helped psychology gain respect as a solid science. His division of mind into two major components, reason and imagination, resonates well with current interest in the functions mediated by the dominant and non-dominant cerebral hemispheres: logical thought and emotional thought, respectively. Bacon also distinguished himself through his humanism: his insistence on compassionate care of suffering patients and his acceptance of euthanasia.

In Italy at this time, Curtius Marinello also made mention of imagination and reason, both faculties being adversely affected in melancholy. The latter was still viewed in humoral terms in Italy and Spain; the by-now-old-fashioned treatment of purging and bloodletting persisted. Tomaso Garzoni was an advocate of mental patients’ being housed in hospitals rather than being penned up in prison-like stronghouses. Even so, his remarks about patients have a contemptuous ring all too common in this era, when the insane were often stockaded in places (as in Vienna’s Narrenturm or Fools’ Tower) where the public could gawk at them as a kind of entertainment. The best-known Italian alienist of the 17th century was Paolo Zacchia (1584–1659), physician to Pope Innocent X. His 1630 compendium on medicolegal questions establishes him as the founder of forensic psychiatry. Zacchia held that certain persons who committed murder could be medically “insane” (in our sense of psychotic, since the term was not purely a legal one as in our day) yet legally sane, hence responsible for their actions.

18th Century

Although by the 18th century everyone recognized the vastness and the roundness of our planet, the world of psychiatry was for all intents and purposes confined to a tiny square, 14° of latitude or longitude on a side, from Edinburgh to Florence and from London to Berlin. With few exceptions, the chief figures in history during this period came almost entirely from the realms of the Protestant Reformation. Aside from Mesmer and Pinel, their names would be unknown except to specialists in the history of our field. We might, to be generous, include the Wild Boy of Aveyron, the feral child treated by Pinel’s pupil, Itard, although the boy (about whom a movie was made some years ago) is much more famous than his doctor.

The 18th century is considered the Age of Enlightenment and was peopled by such prominent scientists, writers,
and philosophers as Voltaire, Rousseau, Newton, Hume, Kant, Moses Mendelssohn, Hegel, Benjamin Franklin, and Goethe. Even in that small square of northwest Europe where the enlightenment shone most brightly, conditions for the institutionalized mentally ill were mostly woeful. Wings for the incurable patients were added in 1730 to London's Bethlem/Maudsley Hospital (built in 1676), but their quarters were still shabby. Many were still in chains, both there and at Paris' Salpêtrière, until the century's end. Bloodletting, emetics, and purges remained the "treatment of choice" almost everywhere; the taxonomy remained brief, composed of mania, melancholy, paranoia, dementia, idiocy, epilepsy, and little else.

**Germany, Switzerland, and Holland**

In the early years of 18th-century Germany, the most influential contributor to the history of psychiatry was Georg Stahl (1660–1734). Strongly opposed to the mechanistic theories of Descartes and Willis, Stahl contended that mind and matter were unified and that the soul was not a spirit peculiar to humankind but a force characteristic of all living beings. For Stahl, mental illness stemmed from a derailment of this life force, such as if one were caught up in a mood or idea that was contrary to the proper direction of the life force. He advocated specific psychological treatment for the mentally ill, as opposed to then popular physical measures (e.g., purges). Stahl's interest in the psyche helped set the stage for the German romanticist movement of the early 1800s, with its intense concern for the individual patient.

Although Goeckel used the word psychology earlier, the German writer Christian Wolff is commonly given credit for coining the term because he used it in a way closer to contemporary usage, that is, as a label for particular studies connected with the mind. His important monographs were *Psychologia Empirica* (1732) and *Psychologia Racionalis* (1734). Wolff spoke of psychology and philosophy as inter-related subjects; it was only later in the 19th century that the two disciplines became more separate, psychology now more allied with physiology and experimental methods.

In Holland, Hermann Boerhaave, whose medical opinions were expressed in almost 1,500 *Aphorisms* (1728), still ascribed to humoral theory. He saw mania and melancholy as different phases of the same condition. To cure melancholy, he recommended taking patients by surprise and immersing them in water, a kind of primitive shock therapy.

Closer to modern shock therapy was the method employed by Leopold Auenbrugger (1722–1809), the originator of auscultation. He described cures of mania via camphor (1776), thus anticipating Meduna’s cure by 150 years—Auenbrugger’s work having simply been forgotten in the long interim.

Equally forgotten is the work of Friedrich Scheide- mantel, who deserves credit as the founder of psychosomatic medicine. In his 1787 book *The Passions as Curative Agents*, he spoke of the harmful effects of the negative emotions (e.g., hate, envy, anger), recommending the positive emotions of joy and laughter as the antidote. In his view, many physical ailments, including colic and women's disorders, were susceptible to cure if one could help the patient to feel joy.

In Switzerland the clergyman Johann Lavater (1741– 1801) wrote extensively on physiognomy, specifically, on the personality characteristics supposedly related to subtle differences in measurements of the head. His work constitutes the bridge from della Porta and Cardanus to Gall and Spurzheim in the next century.

Toward the end of the 18th century, interest shifted in Germany from empiricism to focus on individual persons and their histories, ushering in the period of romanticism. The first book containing lengthy biographies of individual mental patients, for example, was published in 1796 by Christian Heinrich Spiess: *Biographien der Wahnsinningen* (Biographies of the Insane).

**France**

The spirit of the Age of Enlightenment in France was embellished by its two most famous philosophers, Rousseau and Voltaire. Rousseau spoke of our "lost unity with Nature" and on the value of emotion over reason (which placed him in the vanguard of the romantic movement). Voltaire, at once devout yet opposed to organized religion, stood for empiricism and liberal humanism. Their contemporary Condillac espoused materialism, believing that inert matter, if it could somehow be endowed with sensation, might acquire the intelligence of the human mind.

The Lausanne physician Tissot, interested in the connections between physiology and emotion, had ideas about dreams that foreshadowed Freud; dreams carried forward the preoccupations of the day, and nocturnal emissions happened as a result of unfulfilled sexual desires. He saw hysteria as the baleful result of sexual abstinence.

Of the two most famous persons in 18th-century French psychiatry, one was actually an émigré from Austria: Franz Mesmer (1734–1815). Charismatic healer and maverick, Mesmer came to believe in a "universal magnetic fluid" that permeated the universe and had healing powers that could supposedly be harnessed to cure diseases (including mental ones) (Mesmer 1799). Chased out of Vienna because he was accused of touching in a sexual way a young woman whose blindness he cured, he went to Paris. There he gathered around him many devoted disciples, to whom he taught his method. This method consisted of placing the patient in an oaken bucket and of concentrating the “animal magnetism” on the patient via a wand. This practice stirred the ire of the medical establishment, who accused him of charlatanry. To examine the matter, Louis XVI commissioned the great scientists of the day (including Lavoisier and Benjamin Franklin), whose report was submitted in 1784. The conclusion was that the effects of mesmeric treatment were due to the power of the imagination; there was no invisible magnetic fluid. This in no way deterred his disciples, Deslon, Desleuze, Bergasse, and the Marquis de Puységur. The marquis put mesmeric treatment on a more acceptable footing by showing that one did not need the bucket and the wand; it sufficed to rely on the power of suggestion. This improvement was a step on the way to hypnosis, which was perfected in the 19th century. Mesmer and his followers worked chiefly with ambulatory patients suffering from a variety of physical and “nervous” ailments. In the early 1800s, mesmerists often saw their patients five times a week for an hour each, an intensity of individual therapy that may be seen as a foretaste of the psychoanalytic method, with its similar schedule and concentration on one individual.
Although some have proposed Vives (and others, Johann Weyer) as the founder of modern psychiatry, the majority would choose Philippe Pinel, who is in any case much more known to contemporary psychiatrists. Director at various times of two Parisian psychiatric hospitals (the Bicêtre for men, the Salpêtrière for women), Pinel rejected humoral theory and the outmoded treatments it spawned, asserting that mental illness was caused either by hereditary factors or by “intolerable passions,” such as fear, anger, hatred, grief, or elation. Pinel strongly urged removal of the chains from psychiatric inpatients, although he was not the first to do so (Arab and Spanish physicians were doing this in the 15th century). Pinel’s suggestions for treatment were based on rational considerations and direct observation. He advocated a nonviolent approach to violent patients; for example, if many staff members quietly approach such patients they see that they are outnumbered and quiet down without anyone having to touch or hurt them. For severe menstrual pain Pinel recommended early marriage and frequent pregnancy, which may strike us as quaint or even “chauvinistic” but which had the advantage of being effective.

Pinel’s diagnostic schema, although simple, was an advance over earlier nosologies. He spoke of melancholy, mania without delusion, mania with delusion, dementia, and idiotism. He also described hysteria, anorexia, bulimia, hypochondriasis, and (as folie du doute) what we recognize as obsessive-compulsive disorder. The latter could at times take the form of a compulsion to murder, akin to the forensic concept of irresistible urge. Here, Pinel cited the case of a missionary who immolated his children, ostensibly to guarantee them eternal life in heaven.

Pinel’s pupil Jean-Marc Itard brought a compassion and humanism similar to his teacher’s to his work with the mentally retarded. Physician to an institute for the deaf–mute, in 1799 Itard heard of a feral child wandering the woods of Aveyron. Not quite Rousseau’s noble savage, the boy was dirty, unclad, insensitive to heat or cold, and inarticulate except for animal-like grunts. Itard undertook to rehabilitate him, despite the warnings of Pinel, who, with uncharitable candor (and unfortunate accuracy), declared the boy a congenital idiot. Itard took the boy into his home for 2 years. There, guided by the principles of Condillac and by his own naive optimism, Itard succeeded in making the boy tractable, sensitive to changes in temperature, and capable of understanding much of what was said to him. However, the boy never learned to say more than two words: milk and God. Itard’s humane attitudes and his techniques were passed on to his pupil, Séguin, who became the leading figure in the treatment of the retarded in the 19th century.

**England and Scotland**

Among the major forces of the Age of Enlightenment in Britain were the works of Isaac Newton and David Hume. Hume sought to bring the experimental methods employed by Newton to the study of the mind. Hume’s skepticism was manifest in his assertion that mind is not something given us in perception; hence the concept of self is an abstraction, the product of our imagination.

In the early years of the 18th century, the Scottish physician George Cheyne became the first to devote a book to a description of his own nervous disorder: the *English Malady* (1733). No true confessional, the book merely deals with the melancholy, anxiety, and biliousness that affected him for many years. Also, he extended himself an indirect compliment, stating that “Fools, weak or stupid persons are seldom troubled with Vapours or Lowness of Spirits”; rather, these are the afflictions of the highly intelligent.

Richard Mead (1673–1754), a highly respected physician in his day, is noteworthy for two theories he elaborated. One concerned his observation of a certain tubercular patient: as she became delirious, her physical condition improved; when the latter deteriorated again, her mind cleared. Speculating that the body seemed not able to harbor both kinds of illness at once, he thought perhaps giving a mentally ill patient a physical disease on purpose might cure the patient. This theory surfaced again in the 20th century in relation to epilepsy and schizophrenia, which became the (false) rationale for modern shock therapy. Mead also wrote on the influence of the sun and moon on the body, chiefly as concerned menstrual disorders but also various diseases in men that broke out at the full moon. Impressed by this theory, Mesmer plagiarized from Mead in writing his medical school thesis and, as we saw, developed his own theory about extraterrestrial forces affecting the body.

The first extensive text devoted solely to psychiatric conditions was that of William Battie, his *Treatise on Madness* (1758). As director of Bethlehem Hospital in 1742, he found the conditions there so dreadful as to inspire him to build a new hospital (St. Lukes) in 1751. He distinguished between internal and external causes of insanity (the latter related to damage of the brain) and was probably the first to teach psychiatry as a medical school topic in England.

The Scottish neurologist Robert Whytt (1714–1766) worked mostly with the milder mental conditions (in effect, the neuroses): the hysterical, hypochondriacal, and neurasthenic. The last was the term for “nervous exhaustion,” which he thought was caused by different motilities of the nerves. Women were especially vulnerable, he believed, because their nerves were “more motile” than men’s. For similar reasons he thought that women were “more subject to violent passions.”

Charles Moore (1743–1811), a vicar from Kent, wrote a lengthy monograph on suicide, one of the first of its kind. As predisposing factors, he enumerated melancholy, liquor, and a “deplorable want of composure and equanimity of temper,” which Moore thought was endemic among the English. As a cleric, he regarded suicide as an offense against God and society and had some acid remarks about the *Sorrows of Young Werther* (which sparked a wave of suicides in Europe): “a pernicous publication, first broached in Germany by one Goethe.”

Toward the century’s end, John Ferrier (1761–1815) wrote on apparitions, asserting that a “morbid disposition of the brain” might produce the impression of having seen ghosts or specters, even in the absence of delirium or insanity. He originated the term *hysterical conversion*, in which a distant organ acted abnormally, as if out of sympathy with the affected organ, a concept revived by Freud a century later.

**Italy**

In Florence, Vicenzo Chiarugi (1759–1820) was renowned for his humane treatment of the insane and for his opposition to physical restraints. Regarding the latter, he antedated Pinel by a few years, although priority is not so important here.
as the fact that the Enlightenment spurred social reforms in many places at once, independent of one another. Chiarugi became director of the Hospital of Bomfacco (1788) shortly after the appearance of his three-volume work on insanity, Delle Pazzia in Genere ed in Specie. Chiarugi believed that insanity was a consequence of deterioration of the brain and attached great importance to postmortem examination of the brain. As for his humanistic approach, he wrote concerning the duties of his hospital staff: “It is a superior moral duty and medical obligation to respect the mentally ill patient as a person.” His comment serves as a fitting prelude to the emerging movement of romanticism, with its emphasis on the particular histories and sufferings of individual psychiatric patients.

19th Century

In the 19th century, psychiatry began to assume a form with which we, at the beginning of the 21st century, can identify. The term psychiatry itself was used for the first time in the early 1800s. Psychosis took the place of lunacy and insanity—the latter serving mostly as a forensic label. Psychiatry became a recognized branch of medicine, taught in all medical schools. The persecution of witches became a rarity. Psychiatrists concerned themselves increasingly with the mildly ill, not just with hospitalized psychotic patients. The sanitariums were much improved, as was the care of the retarded. America came into the picture at mid-century, helped in part by the steamboat and the railroad, facilitating the exchange of ideas of practitioners within each country and across the ocean.

German-Speaking Countries

For roughly the first half of the 19th century, German philosophy was preoccupied with the irrational, the strivings of the individual, and the wish to return to nature. It is this attitudinal shift that became known as romanticism. The focus in psychiatry was on dreams, sexuality, and hidden desires (for which the term unconscious came into use). Schopenhauer’s will, to which reason and knowledge were subservient, resembles, in the language of Freud, the concepts of libido and unconscious.

One of the most important contributors in the romantic period was Johann Reil (1759–1813). Reil originated the term psychiatry. Reil (1803) spoke of a basic feeling of being and experience, the Gemeingefühl, similar to our sense of identity, loss of which was associated with psychosis. Reil was among the first to employ occupational therapy, as well as music and drama therapy, as ways of reeducating patients to develop more adaptive ways of coping.

Other figures of the romantic period include Carl Carus, Ernst von Feuchtersleben, and Eduard Beneke. Carus saw the unconscious as the “fundamental biological force,” one part of which remained forever inaccessible. Von Feuchtersleben viewed psychotherapy as a reeducative process for helping patients untangle the problems resulting from their disordered personality. In opposition to Descartes, he saw mind and body as one. For Beneke, abnormal ideas could become translated into bodily reactions—establishing him as a psychosomaticist. Ethics derived from natural law because humans are creatures of nature, our ethics therefore an expression of our need to get along with our fellow humans.

A forerunner of the psychoanalytic movement (although never credited as such), Johann Heinroth (1773–1843) developed a theory of mind embodying a tripartite structure: the instinctual forces, consciousness (Bewusstsein or das Ich), and the Ueber-uns (that which is “over us”) (Heinroth 1818). Besides anticipating Freud’s 1923 division of mind into id, ego, and superego, Heinroth introduced the notion of internal conflict, for example, that between sin and conscience. He stressed the need to treat patients according to their individual qualities and symptoms, utilizing kindness and warmth with some, firmness with others.

Anxiety secondary to sexual unfulfillment was recognized by Karl Ideleler, director of Berlin’s Charity Hospital. In 1841 he published a book containing lengthy biographies of 11 patients, the first such book by a psychiatrist.

Beginning in the 1840s, the pendulum swung toward the side of biological or experimental psychiatry. Gustav Fechner (1801–1887) studied the relationship between the intensity of external stimuli and the strength of the corresponding sensation. He enunciated a pleasure principle and introduced the concept of repetition, later reworked by Freud as the repetition compulsion: the tendency to repeat earlier patterns, especially ones involving traumatic experiences.

The most important figure in this new epoch was Wilhelm Griesinger (1817–1868), whom many consider the founder of biological psychiatry. For Griesinger, mental disease was somatic disease, a decidedly monistic position. Neuropathology and psychiatry were one and the same field. He gave great importance to temperament, always commenting on each patient’s temperament (e.g., sanguine-octhleric) in a case description. Impressed by Calmeil, who showed the connection between general paresis and a certain brain pathology, Griesinger (1871) concluded that all mental disease must stem from abnormalities of brain cells; there were no “functional” disorders.

Other biologically oriented physicians of this era include Theodore Meynert, Karl Wernicke, PE Flechsig, and Wilhelm Wundt. Meynert outlined different layers of the cerebral cortex according to cell type, Wernicke developed a theory of associations based on cerebral histology, Flechsig helped define projection and association areas in the cortex and distinguished motor from sensory aphasia, and Wundt studied the phenomenon of psychological associations.

In the second half of the century, the towering figure of biological psychiatry was Emil Kraepelin (1855–1926) (Figure 14–1). A student of Wundt and Flechsig, he was also inspired by Morel’s 1852 treatise on démence précoce, concerning intellectual deterioration beginning in adolescence. A great systematizer and diagnostic “lumper,” Kraepelin unified nosology among the psychoses, placing catatonic, hebephrenic, and the various paranoid conditions under the rubric dementia praecox (Kraepelin 1909–1915). Kahlbaum (1874) had earlier described catatonia; his pupil, Hecker, hebephrenia. Kraepelin assigned the task of finding the histological abnormalities he assumed patients with praecox exhibited to Alois Alzheimer. Although Alzheimer was unsuccessful in that task, he did discover characteristic lesions in certain cases of senile dementia, the eponymous Alzheimer’s disease. Kraepelin also described subtle or borderline forms of the major psychoses, particularly the abnormal temperaments associated with manic-depression: (hypo)manic, depressive, irritable, and cyclothymic. Because of Kraepelin’s emphasis on precision and objective
diagnostic criteria, current editions of the DSM are considered neo-Kraepelienian.

Toward the turn of the century the works of Krafft-Ebing and Emmeringhaus appeared. Krafft-Ebing described a broad range of sexual disorders including the paraphilias; Emmeringhaus put child psychiatry on a separate footing, noting that disorders in children were often incommensurate with those typical of adults.

In the history of psychiatry the only name to become a household word is that of Sigmund Freud. Born in Pribor (Czechoslovakia) in 1856, he moved with his family to Vienna when he was 3 years old. In 1876 as a student of Bruecke, Freud joined his mentor in the search for neurophysiological substrates for psychological processes. During the next phase of his work, with Meynert (1882–1886) he became codiscoverer of the anesthetic properties of cocaine. In 1886 he studied hypnosis and hysteria under Charcot in Paris. Inspired by the power of hypnosis to relieve hysterical symptoms, he returned to Vienna and formed a friendship with Josef Breuer, who was sympathetic to the new methods. In 1893 Breuer and Freud published a paper on the psychic mechanisms of hysteria, a transitional work between hypnotherapy and psychoanalysis proper. Discovery that the unconscious could be mined through free association with even better effect than by hypnosis came in 1895. Although he never relinquished his interest in neurology, Freud realized that the science of the day could not supply the answers to the questions he was posing. His writing turned more psychological and remained so to the end. His most enduring work is his Traumdeutung, the Interpretation of Dreams (1899, but printed as 1900). The meaning of dreams could be plumbed via free association, unlocking hidden conflicts between different agencies of the mind (usually related to forbidden sexual wishes and the dictates of conscience).

Making the unconscious conscious within the context of the transference relationship with the analyst was the key to the psychoanalytic cure for the various psychoneuroses: milder conditions such as phobic, obsessive, hysterical, or depressive character disorders. Freud believed that psychotic patients were unable to form a transference and were thus not amenable to the analytical method. In time psychoanalysis became both a new psychology (for understanding how the mind works) and a new therapy for the psychoneuroses. In 1923 Freud proposed a tripartite model of mind: the instincts constituting the id portion, the conscience constituting the superego, and with the ego as the reality-based agency that mediated between them. By the time of Freud’s death in 1939, there were psychoanalytic institutes for training and treatment throughout Middle and Western Europe and in the US. Although many of Freud’s assumptions have had to be revised or discarded, there remains a strong foundation having to do with the hidden motivations that direct people’s behavior. Before Freud, case descriptions of patients lacked details about childhood fantasies and traumatic experiences, rendering those accounts arid and unsatisfying. It was Freud’s return to the attention on the individual that lent to his psychology its richness and fascination. One might speak of his having ushered in a new period of German romanticism, which in the late 20th century has been largely pushed aside by the renewed interest in biological psychiatry; the same evolution we saw unfold in the 19th century.

France

In France, psychiatry evolved in a fashion almost opposite to that of Germany: the emphasis during the first half-century was on biological aspects; during the second half there was less “neurologizing” and more attention to individuals.

In 1803 the philosopher Pierre Maine de Biran outlined three types of memory, using a classification that strikes us as modern: mechanical or habit memory, sensitive memory (dealing with the recollection of sensations and emotions), and representative memory (long term, associative). Another philosopher, P.J.G. Cabanis, in a work devoted to sensation (1802), also outlined various instincts, subserving self-preservation, movement, and nutrition. He noted a similarity between madness and dreaming and agreed with Pinel that “imbeciles often have a diminution in their brain size that accounts for their limitation”—an appealing notion at the time because it seemed so scientific.

Along similar lines the pseudoscience of phrenology (Figure 14-2) became enormously popular, stimulated by the publications of Franz Gall and Caspar Spurzheim, who claimed to be able to predict personality from the shape of the head (as though the latter reflected the brain’s “37 organs”—for reverence, conscientiousness, amativeness, acquisitiveness, and so on). Misguided though these efforts were, they led the way to more serious research on brain mapping a generation later.

Serious work was already being done in the area of general paresis by Calmeil (1826) and Antoine Bayle, who discovered a link between certain forms of meningitis and the disorder that would later be identified as neurosyphilis, when in 1913 Noguchi demonstrated the responsible spirochete—the whole sequence of discoveries constituting a triumph of biological psychiatry.

The most famous French psychiatrist of this era was Jean-Etienne Esquirol (1772–1840). A disciple of Pinel, he made contributions to descriptive psychiatry, originated the term hallucination, and with his colleague Guillaume Ferrus helped bring about law reforms in 1838 that led to improvements in asylums. Esquirol’s nosology recognized
1. Organ of destructiveness
2. Organ of amativeness
3. Organ of philoprogenitiveness
4. Organ of adhesiveness
5. Organ of inhabitiveness
6. Organ of combativeness
7. Organ of secretiveness
8. Organ of acquisitiveness
9. Organ of constructiveness
10. Organ of cautiousness
11. Organ of love of approbation
12. Organ of self-esteem
13. Organ of love of approbation
14. Organ of reverence
15. Organ of firmness
16. Organ of conscientiousness
17. Organ of hope
18. Organ of marvellousness
19. Organ of ideality
20. Organ of mirthfulness or gayness
21. Organ of imitation
22. Organ of individuality
23. Organ of configuration
24. Organ of size
25. Organ of weight and resistance
26. Organ of coloring
27. Organ of locality
28. Organ of order
29. Organ of calculation
30. Organ of eventuality
31. Organ of time
32. Organ of tune
33. Organ of language
34. Organ of comparison
35. Organ of causality

Figure 14–2  A phrenological map of the head, as depicted by Theodore Poupin, based on the works of Gall, Spurzheim, and Lavater. Each of the 35 regions was considered a separate “organ,” controlling a different characteristic of the personality or the mind. (Source: Poupin T [1837]. Courtesy of WW Norton & Company; excerpt from Healing the Mind—A History of Psychiatry from Antiquity to the Present by Michael H Stone, M.D. Copyright (c)1997 Michael H Stone, M.D., p 89.)

délire général (all-encompassing psychosis), délire partiel (which later became monomanie, delusions in just one area), and affaiblissement intellectuelle. Among the many délires partielles were kleptomania and pyromania, terms still in use; his term for psychotic depression, lypémantie (“grief-madness”), never enjoyed wide use (Figure 14–3).

In his important 1838 textbook Esquirol also addressed the issue of suicide and provided some statistics on methods used and rates in various communities.

Apropos hallucinations, Briërre de Boismont in his 1845 monograph on the subject mentioned that ecstasy, especially religious ecstasy, predisposed to hallucinations, as in the case of the 18th-century visionary, Emmanuel Swedenborg. Such persons need not be considered mentally ill. He alludes also to the hallucinations of Jeanne D’Arc who, at about age 12 years, heard a voice from the sky tell her, “Jeanne, it is you whom the Lord of the Heavens has chosen to restore the kingdom of France and to be the help and support of King Charles.” A similar point was made by another French alienist, Louis-Rufin Szafkowski who, in his 1849 book on hallucinations, distinguishes between hallucinations of reason versus hallucinations of madness. The former type was applicable not only to Jeanne D’Arc, but also to Luther (who envisioned the Devil standing in front of him) and Mahomet, whom the author regarded as a supranormal man given to voices he ascribed to the angel Gabriel, dictating to Mahomet what was to become the Koran. Such phenomena were understood by these French alienists as in keeping with the culture of the times in which these great figures lived.

At mid-century, Jean-Pierre Falret and J. Baillarger each proposed that mania and melancholy were two forms of the same process, to which Falret gave the name folie circulaire and Baillarger folie à double forme. The two entered an acrimonious dispute over priority and over which was the more accurate term; both deserve credit for clarifying the nature of what we now call Bipolar Disorder, DSM-IV-TR.

J. Moreau de Tours, a pupil of Esquirol, described the effects of hashish, likening the altered mental state to the dream state. Benedict Morel wrote a general text on mental illness in 1852, in which he described, under the title démence précoce (the inspiration for Kraepelin’s dementia praecox), the deterioration of the intellect in certain adolescents. Morel attributed the condition to hereditary “degeneration”; the fathers, he thought, were often alcoholic (Morel 1860).

A number of French alienists gave attention to forensic matters. Persons given to outbursts of homicidal or suicidal behaviors in an impulsive manner, yet without seeming engulfed in madness, were described under the heading of monomanie homicide. Some of the cases mentioned by Dagonet in his 1862 psychiatric textbook resemble our current “psychopaths,” in that the patients showed no regret or remorse, and were calm and without fear when they committed murder. Yet they differed from the cold psychopath, in that they stayed near the corpse, and confessed readily
to the magistrates, condemning the acts they had just carried out. One such man, in a fit of jealousy over rejection by a woman, tried first to commit suicide. He then contemplated killing the woman, so that he would be caught and executed. Later, horrified by that idea, he planned to kill a prostitute, regarding prostitutes as symbols of the source of his anguish and sexual frustration. We nowadays confront such patients usually in the forensic hospital: persons who have assaulted or murdered under the influence of strong passion or despair—seriously depressed, but not psychotic. Other examples where psychiatry and the law intersect, and which were addressed by mid-19th-century psychiatry, concern brain damage from "general paralysis" (tertiary syphilis), mental retardation, erotomania, and religious delusions. The subject of infanticide was taken up by two French authors, Ambroise Tardieu (1868) and Paul Brouardel (1897). The majority of Tardieu’s cases concerned young unmarried women who suffocated their newborns (in what we now call neonaticide), fathered all too often by the master of the house where they had been employed as maidservants.

Other important French contributors include Paul Broca, who outlined the "speech area" in the cerebrum; Briquet, in whose 1859 treatise on hysteria Briquet’s syndrome is described (multiple somatic complaints for which no physical cause can be found); Edouard Séguin (1866), who instituted humane reforms in the care of the retarded (substituting coaxing and kindness for corporal punishment); Henri Le Grand du Saulle, whose 1866 descriptions of obsessive-compulsive disorder (folie du doute) are unparalleled in detail; and Georges Gilles de la Tourette of the eponymous Tourette’s disorder (tics and compulsive scatologia).

A source of inspiration for Freud’s landmark treatise on dream interpretation was a most unusual book by a French aristocrat, Hervé de Saint-Denys (1867), who felt he could direct the content of his dreams by conscious effort before going to sleep. To this end he kept a diary of many of his dreams—something that almost no one had done before. Saint-Denys pictured dreams as an amalgam of images derived from the brain’s vast scrapbook of visual memories stemming from the whole course of one’s life. He understood something of the phenomenology of dreams, but little of their psychology. Consider this example from Part 3 of his book: “I saw a young woman dressed in an old-fashioned style, playing with pieces of red-hot metal—which in no way injured her. Whenever she touched them, long tongues of flame remained momentarily at the edges of her fingers. When she rubbed her hands against one another, a shower of sparks scattered noisily from them.” Viewed through the Freudian prism the dream seems full of allusions to sex and passion. However, the author provides us with no associations. It was a mark of Freud’s genius to realize that dreams could be unraveled and understood only through the associations of the dreamer—associations that are unique to each person, and not to be decoded via the popular dream “dictionaries” of his day.

It was from the great neurologist Jean-Martin Charcot (1825–1893) that Freud learned about hypnosis and hysteria. Freud then studied with the famous hypnotherapists in Nancy, Liébault, and Bernheim. Charcot also influenced the experimental psychologist Théodule Ribot, who envisioned a continuum between normal and abnormal personality (a term he used in 1885). Influenced also by Darwin, Ribot wrote on the importance of heredity in determining personality.

**England, Scotland, and Ireland**

In Great Britain there was little attention to the individual throughout the 19th century. Much more consideration was given to topics like taxonomy, heredity, and asylum reform (including the use of nonrestraint). Many of the prominent physicians and alienists trained or taught in Scotland. Edinburgh’s William Cullen introduced the term neurosis as a general term for nonfebrile conditions of the brain and nervous system. Only later did it become (an equally vague) term for mild characterological disorders amenable to psychoanalysis. Joseph Cox, also from Scotland, was the first in Britain to study medicine with the avowed purpose of
working with the mentally ill. He devised a rotating chair by which patients were swung (and frightened), so as (literally) to draw out disturbing thoughts and emotions. William Hallaran in Ireland also advocated “swinging” but along with it occupational therapy and brief stays in the hospital.

One of the early systematizers was Thomas Arnold, a pupil of Cullen, who enumerated many varieties of “insanity” that fit well with our concept of personality disorders. Similar to our terms schizoid, paranoid, histrionic, and narcissistic, for example, were Arnold’s descriptors misanthropic, suspicious, amorous, and arrogant.

The nonrestraint movement gained ground in England, spurred by such men as William Tuke (1813), the Quaker tea merchant who founded the York Retreat, and John Conolly (1830), who removed restraints at the Hanwell Asylum.

John Haslam (1766–1844) stands out for his excellent descriptions of both general paresis and what would later be called schizophrenia, while he was medical director of Bethlem Hospital. In 1810 he published the first book devoted to a single case of insanity—persecutory paranoid in form—concerning a man who thought that there was an “infernal machine” controlling his life and subjecting him to all manner of excruciating tortures. The case resembled the “influencing machine” patient described by Viktor Tausk in the 1920s.

The originator of the term moral insanity was James Prichard (1786–1848), the director of several hospitals in England. A systematizer like Arnold, he followed Hume’s division of mental life into thought, affect, and behavior. Aberrations of feeling he spoke of as examples of moral insanity, using “moral” in the French sense (morale) of one’s spirits or general mood. Some of the cases he described under this heading did show the lack of compassion we associate with the psychopath (in contemporary parlance), although mostly Prichard was referring to cases of affective disorder (Prichard 1835).

A few years later William Browne, superintendent of the Montrose Asylum in Edinburgh, spoke of delinquency and moral insanity in the same breath. A great reformer of asylums, Browne emphasized kindness toward the patients and involving them in useful occupations. Although he was visited by Dorothea Dix in 1855, he was no admirer of America: “The fact cannot be overlooked,” he said, “that the source of the population which has been flowing to America has been impure and poisoned.”

Modern research on hemispheric asymmetry seems to have been anticipated in the work of Arthur Wigan (1785–1847). Based on autopsy findings of patients with lesions in one hemisphere, he postulated that the two hemispheres amount in effect to two separate brains: one “superior in its rational powers,” the other presiding over the irrational.

The first to use the term hypnosis was the Scottish physician James Braid (1795–1860). Intrigued with mesmerism after a lecture in 1841, he became an effective hypnotizer, curing many of the milder nervous afflictions but incurring the wrath of the medical establishment (Braid 1843). The tremendous enthusiasm generated by Braid and other Mesmerians led to the publication of an important journal, The Zoist (1843–1856), whose 13 volumes contain numerous testimonials to the efficacy of the mesmeric/hypnotic method in the cure of such conditions as blindness, deafness, delirium, epilepsy, headache, hysteria, palsy, rheumatism, and ulcers.

The medicolegal consequences of insanity were reexamined by Forbes Winslow (1810–1874) in a book appearing in the same year (1843) as the famous M’Naghten case. Legal insanity was defined in that case as a state wherein a perpetrator is unable, because of mental disease, to recognize the nature of the act or that it is wrong. This has remained a standard throughout much of the Anglo-American community.

The work of Charles Darwin (1809–1882), the most well-known man of science in 19th-century England, stimulated psychiatric research along two fronts: one concerning adaptation and heredity (the latter study helped immeasurably by Darwin’s contemporary Gregor Mendel), the other emotions. The two areas are interrelated: our facial and bodily expressions, treated in Darwin’s 1872 essay, all have their survival value; they help us gauge the friendly from the hostile stranger, they elicit sympathy when others show grief, and so on. Both psychogenetics and behavioral theory and therapy received much of their impetus from Darwin’s discoveries.

Darwin’s cousin, Sir Francis Galton, published a book in 1869 (based on an earlier article endorsed by Darwin), Hereditary Genius. Standardized intelligence tests not yet having been created, he drew up his own bell curve, concluding that a small percentage of the population were either geniuses or idiots. His avowed purpose was to contribute to the eventual betterment of humankind through eugenics. (Owing to the atrocities by the Nazis under the aegis of eugenics, the whole field has fallen into disrepute.)

Two prominent figures at the century’s close were Henry Maudsley and John Hughlings Jackson. Maudsley saw mental disease as organic brain disease. He wrote on the “insanity of early life,” 20 years before Emminghaus’s monograph, and was aware that dreams partake of “ancestral modes of thought” in which imagination gains ascendancy over reason. Hughlings Jackson, inspired by Darwin’s work on evolution, spoke of the nervous system as organized, via evolution, from the most to the least organized and from the most to the least complex. For example, the highest, cortical centers are least organized at birth, becoming more so throughout life.

**United States**

Although the US is now the major source of new knowledge in the mental health disciplines, at the debut of the 19th century it was just beginning to make its presence felt.

Philadelphia’s Benjamin Rush (1745–1813) (Figure 14–4), the first US psychiatrist of prominence, assumed directorship of the Pennsylvania Hospital in 1787. Still adhering to the theory that abnormalities of the cerebral vasculature underlay mental disease, Rush thought that mania represented inflammation of those vessels. He coined many diagnostic terms: manicula, for mild manic disorders; tristemania, for depressive states; and even home-phobia, for men who preferred the tavern to the home. His suggestions for treatment were paradoxical; he favored removal of the chains, yet also recommended barbaric measures like dunking under water and total immobilization in the tranquilizing chair (see Figure 14–5).

The first psychiatric book published in the US was a reprint of an English work, *A View of the Nervous Temperament*, by Thomas Trotter (1760–1832). Trained in Edinburgh, Trotter wrote his medical thesis on alcoholism, which he considered a disease rather than merely degeneracy. As a
Foundations

Woodward (one of the founders of the Hartford Retreat), Thomas Kirkbride, Amariah Brigham, Isaac Ray, Pliny Earle, and Luther Bell. Brigham was the first editor of the American Journal of Insanity (in 1844), forerunner of the American Journal of Psychiatry.

Isaac Ray, director of Butler Hospital in Providence, was the most admired psychiatrist at mid-century. His 1839 treatise Medical Jurisprudence of Insanity was the most important US work on forensic psychiatry. He favored restraint, arguing that Europeans, even when insane, were more obedient than Americans.

The most dramatic psychiatric case was that of Phineas Gage, a Vermont railroad worker through whose skull a 3-foot tamping rod passed during a blasting powder accident (see Figure 14–6). Although Gage miraculously survived, he underwent a marked personality change, becoming fitful, irreverent, and rude, whereas he had been temperate and shrewd beforehand. It has been shown that the lesion was in the ventral and medial sectors of the frontal lobes, which appear to subserve social decisions and moral choices.

The 19th-century American relevant to the history of psychiatry who comes closest to being a household word was not a psychiatrist but a Boston schoolmistress turned reformer: Dorothea Lynde Dix. A woman who had struggled with her own serious depression, she had deep compassion for the mentally ill, although she was 39 years old before she actually witnessed the wretched conditions of the asylums. She then addressed the state legislature, at first in Massachusetts, later in other states, and also in Scotland and England (where she met Samuel Tuke, son of the founder of the York Retreat). Her oratory and her zeal (she was not above portraying the conditions in the hospitals as a little worse than they were to maximize her impact) led both to improvements in existing facilities and to the construction of dozens more. Here is a brief excerpt from her remarks in 1848 to the assembly in North Carolina (where a hospital named after her exists to this day):

In the Providence of God, I am the voice of the maniac whose piercing cries from the dreary dungeons of your jails penetrate not—your Halls of Legislation. I am the hope of the poor crazed beings who pine in the cells, and stalls and cages, and waste-rooms of your poor-houses. I am the Revelation of hundreds of wailing, suffering creatures, hidden in your private dwellings, and in pens and cabins—shut out from all healing influences, from all mind-restoring cares.

The first meeting of what was to become the APA took place on October 16, 1844 in Philadelphia. The most well known in our time of the 13 founders are Samuel Woodward (one of the founders of the Hartford Retreat), Thomas Kirkbride, Amariah Brigham, Isaac Ray, Pliny Earle, and Luther Bell. Brigham was the first editor of the American Journal of Insanity (in 1844), forerunner of the American Journal of Psychiatry.

In the Providence of God, I am the voice of the maniac whose piercing cries from the dreary dungeons of your jails penetrate not—your Halls of Legislation. I am the hope of the poor crazed beings who pine in the cells, and stalls and cages, and waste-rooms of your poor-houses. I am the Revelation of hundreds of wailing, suffering creatures, hidden in your private dwellings, and in pens and cabins—shut out from all healing influences, from all mind-restoring cares.

In the Providence of God, I am the voice of the maniac whose piercing cries from the dreary dungeons of your jails penetrate not—your Halls of Legislation. I am the hope of the poor crazed beings who pine in the cells, and stalls and cages, and waste-rooms of your poor-houses. I am the Revelation of hundreds of wailing, suffering creatures, hidden in your private dwellings, and in pens and cabins—shut out from all healing influences, from all mind-restoring cares.

One of the men who “caught the fever” from Dix’s impassioned pleas was Thomas Kirkbride, who became the guiding spirit of model hospital building in the 1870s.

Several important contributions in the latter half of the century came from neurologists. Silas Weir Mitchell, besides writing Diseases of the Nervous System, Especially in Women (1881), described a case of “double personality” (1889). The patient, Mary Reynolds, had moved to Pennsylvania from England as a child. Although melancholic and avoidant ordinarily, absorbed in Bible reading all day long, at age 18 years she began having “hysterical attacks,” after which she lost all memory of her past, even how to speak, such that she had to be taught language from the beginning.
In this state she was prankish and cheerful. A few months later, after a prolonged sleep, her former self would reappear. These switches recurred regularly till age 36 years, when she remained in her cheerful, buoyant state till her death at age 61 years. There is no evidence as to whether she had been an abuse victim, as is so regularly the case with patients with multiple personalities in our era.

The other neurologist, George Beard, achieved greater fame, if less respect, than Mitchell, for his somatic treatment based on electricity. Beard introduced the term neurasthenia, similar to Whytt’s nervous exhaustion. He began using electricity to provide a “tonic” for depressed, lethargic patients, chiefly in the form of faradic stimulation. Soon faradic machines were sold and used all over the US, as a cure for a whole dictionary of disorders from ataxia to paralysis (see Figure 14–7). Although in reality no more than mechanical “snake oil,” electrical treatment kept alive the tradition of biological or somatic psychiatry, which would soon become the respectable branch it is today.

Other Countries

Immensely famous in late 19th-century Europe, Cesare Lombroso, professor of anthropology in Torino, wrote extensively on physiognomy and on hereditary genius. Convinced that there was a strong correlation between certain facial configurations and criminal tendencies, Lombroso amassed a vast collection of etchings of various criminals, who looked unusually mean, hostile, and untrustworthy. This lent to his work great popularity, because it pleased the “moral majority” of his day to think that criminals looked different from respectable people. Meanwhile, Lombroso’s other thesis—that genius was akin to madness—was also pleasing to ordinary people, as though the distance that separated them from brilliance also separated them from insanity. With his colleague, Guglielmo Ferrero, Lombroso also devoted attention to female criminals (1893). In their compendium they provided data on weight, height, facial beauty or the lack of it—on large numbers of female offenders (many of whom were prostitutes), along with data of normal women “controls.” The differences in the two groups strike us as at most—minor, and often, quite biased. Yet the meticulousness of their approach set the tone for the methodical examination in the years to come—of variables of much greater importance and of a less prejudicial nature—in the domain of research on the criminal mind.
The great Spanish neurohistologist, Ramon y Cajal, contributed importantly to psychiatry by placing on a firmer scientific footing the inextricable linkage between brain and “mind.” His pioneering work (Ramon y Cajal 1889) paved the way to the research on the synaptic cleft and on the various neurotransmitters, as carried out in the 1960s and beyond by Hornykiewicz, Schildkraut, Kety, Solomon Snyder, and others.

In Russia, work that was to lead to behaviorism and behavioral therapy was being carried out on conditioned reflexes, first by Ivan Sechenov and then by his more famous pupil Ivan Petrovich Pavlov (1849–1936). Both men held that psychological acts were merely the final expression of external stimuli impinging on our sense organs. Pavlov showed that repetitive learning could be used to create conditioned reflexes, built on the organism’s unconditioned reflexes. In his famous experiments (for which Pavlov won the Nobel Prize), a dog learned to salivate to the sound of a bell, if the bells were rung simultaneously with the presentation of food (Pavlov 1898).

**20th Century**

As the 20th century drew to a close, we began to see trends that were less readily apparent a generation ago. The century’s two halves were dramatically different, in psychiatry as in everything else. At mid-century, World War II had just ended and had just ushered in the atomic age. Afterward the world found itself on the steep slope of the S curve of population. Jet travel, television, fax machines, and now e-mail have enhanced communication beyond the wildest dreams of our grandparents. Psychiatry is now truly worldwide. Although there are many countries with few psychiatrists, there are few countries with no psychiatrists. The term *international*, as applied to psychiatric meetings, used to be a conceit indulged by the few Americans, British, French, and Swiss who actually attended. Now participants may come from 30 or 40 countries, representing all six continents. Excellent and original work is being done in so many places that a proper history of psychiatry’s last half-century would be a multiauthored production only a little less voluminous than the *Oxford English Dictionary*.

**The Early Years**

In 1903 Alfred Binet published his important study on intelligence: produced with the help of his colleague T. Simon, the famous Binet–Simon test appeared in 1905, permitting greater precision and meaningfulness than were possible in Galton’s day. Pierre Janet (1851–1947) emerged as a key figure in descriptive psychiatry; among his numerous books were one on *idées fixes* and others on obsessions, religious mania, hysteria, and personality (Janet 1890). Treatment, for Janet, consisted in helping patients express “fixed ideas” hitherto locked in their “subconscious.”

In 1905 Freud published his landmark *Three Theories of Sexuality*, in which he discussed the sexuality of children and the (as he saw it) inverse relationship between the neurones and the perversions (see Figure 14–8). The case of “Little Hans”, a 5-year-old boy whose Oedipus complex was resolved via Freud’s discussions with the father, also appeared. In 1909 Freud lectured at Clark University in Worcester, accompanied by Jung and Ferenczi, introducing psychoanalysis to American shores.

Adler coined the term *inferiority complex* in his 1907 book explicating his theory that the crucial dynamic behind human behavior was the wish for power.

In Russia, Vladimir Bechterev developed his psychoreflexology (in the tradition of Pavlov) and effected cures of alcoholism with aversive conditioning.

A former mental patient, Clifford Beers, wrote a book, *A Mind That Found Itself* (1909), describing his (manic) psychosis and recovery—despite the degrading circumstances of his hospitalization. He lectured widely afterward and was instrumental in effecting salutary changes in mental hospitals.

Shortly before Eugen Bleuler’s epoch-making monograph on the “group of schizophrenias,” a work that unified under one rubric the many varieties of delusional syndromes then recognized, Sérieux and Capgras published their exhaustive treatise on the paranoid syndromes: *Les Folies Raisonnantes* (1909). Some of their examples were to be subsumed under the heading of “Capgras’ Syndrome”—in which the patient insists that the person in front of him (a mother or wife, e.g.) is not “really” that person, but an impostor dressed up to resemble the person in question. In one of their clinical examples, a woman with what we would call paranoid schizophrenia would examine minutely the letters she received in the hospital from her family. She made interpretations based on the vagaries of punctuation and spelling. When her brother wrote, for example, “We are eager for your recovery,” she insisted that the period (“point” in French) at the end of the sentence was bigger than ordinary, and therefore signified: “Nous ne désirons point ta guérison.” (“We don’t want you to get better at all.”)

The decade of the 1910s saw a break in Freud’s relations with Adler (because of his overemphasis on the power motif) and with Jung (because of his preoccupation with mystical themes of a collective unconscious). Karl Abraham,
who remained loyal, wrote on the oral, anal, and genital character types adumbrated in Freud’s developmental track. Freud’s papers dealt with the unconscious homosexual themes in paranoia (the Schreber case), grief reactions (mourning and melancholia), and obsessional neurosis (the “Wolf Man”). Alfonse Maeder and Poul Bjerre took issue with Freud’s dictum that schizophrenic patients could not form a transference or benefit from psychoanalysis; both men reported on psychoanalytic “cures” of patients they considered schizophrenic (1911).

The Hungarian lay analyst Melanie Klein (1882–1960), after working with Ferenczi and Abraham, moved to England, where she set up a psychoanalytic group in opposition to that of Anna Freud and Ernest Jones. Klein’s interest was in early object relations and the analysis of children. Her theories are interpersonal, focused on the first few (preoedipal) years of life, and are weighted far toward the psychological (while ignoring heredity and constitution). Klein’s theories concerning developmental stages in infancy, which she characterized as the paranoid–schizoid position, and a later depressive position, have been influential in the works of later psychoanalytic theoreticians, including Otto Kernberg, and more recently, Nancy McWilliams, who speak of the therapeutic progress one hopes to achieve with, for example, paranoid patients, as exemplifying the passage from less to more mature positions, as Klein had outlined.

In the US Isador Coriat, another enthusiast for the analytical treatment of individuals with schizophrenia, founded the American Psychoanalytic Institute.

John Watson (1878–1958) founded behaviorism (1913), which stressed the observable rather than the unconscious. He saw phobias as arising out of early conditioning, curable by desensitization. His work influenced other behaviorists, Thorndike and Skinner.

In Zurich Eugen Bleuler became director of the Bürghölzli clinic, where he worked intensively with patients with dementia praecox, which he was soon to rename schizophrenia in his 1911 monograph in which he outlined the “four A’s” of its diagnosis: autism, associational loosening, ambivalence, and affect inappropriateness. His criteria were broader than those of Kraepelin and lent a more hopeful outlook to prognosis. Many of his “good outcome” patients with schizophrenia (including the composer Robert Schumann) would be considered bipolar according to current diagnostic standards.

In Germany, Julius von Wagner-Jauregg (1857–1940) introduced malaria therapy for syphilis, on the grounds that leucitic patients who were febrile with an infection seemed to get better. There is no actual evidence that this was so, yet he was awarded the Nobel Prize in 1927. Elsewhere in Germany, Ernst Ruedin published data on the siblings of yet he was awarded the Nobel Prize in 1927. Elsewhere in luetic patients who became febrile with an infection seemed introduced malaria therapy for syphilis, on the grounds that current diagnostic standards.

Robert Schumann) would be considered bipolar according to the biological, must be taken into account in understanding any patient. He spoke of reaction types rather than of diseases. A schizophrenic “reaction” might arise out of adverse hereditary factors yet could also arise out of a combination of other adverse environmental factors. This seemed a more hope-inspiring view at the time and dominated US psychiatry until the last generation.

There were advances in group therapy, thanks to the work of Jacob Levi Moreno, who introduced psychodrama as a way of dramatizing and relieving neurotic conflicts, and also of Samuel Slavson, who popularized group therapy for both children and adults.

Morton Prince (1854–1929) is remembered for his detailed account of a multiple personality with “alters”: Sally Beauchamp, whose main self was playful and angry, and her two alters, fearful and suggestible, respectively.

The Hungarian psychiatrist Ladislaus von Meduna used camphor to induce seizures in patients with schizophrenia (on the false theory that schizophrenia and epilepsy could not occur in the same patient). In Italy, Ugo Cerletti collaborated with L. Bini in developing electroshock therapy for use with schizophrenic and manic–depressive patients. Psychoanalysts who worked with schizophrenic patients were beginning to realize that more active, supportive interventions were necessary; Gustav Bychowski, Gregory Zilboorg,
and Kurt Eissler were at the forefront of this movement. Leland Hutt in New York advocated for such patients an approach emphasizing reeducation and removal from the stressful environment.

The first twin study on the inheritance of schizophrenia was carried out in Munich by H. Luxenburger (1928). He found a concordance rate among monozygotic twins of 67%.

In the area of forensics, the most notable contribution was that of August Aichhorn (1878–1949), who set up a model reformatory for delinquent adolescents. His famous book *Wayward Youth* (1925) reflects his beliefs in the efficacy of warmth and understanding, along with a demonstration of the superiority of a value system based on honesty. In the years that followed, many centers were built on this model.

**The Middle (Including the War) Years**

The topic of personality received considerable attention during the 1930s. Gordon Allport and Henry Odbert, psychologists at Harvard, combed the unabridged dictionary and came up with 18,000 trait words. Later investigators drew on this list in condensing the many adjectives into more manageable lists of personality factors, which might number 20 or 30 or 60. In Sweden, Henrik Sjöbring broke personality down into a small number of crucial dimensions: validity, solidity, and stability. Cyclothymic patients, for example, he considered “substable.”

In the area of psychoanalysis, Freud’s eldest daughter, Anna Freud, made notable contributions in both child psychiatry and the elucidation of defense mechanisms. Her *Ego and the Mechanism of Defense* (1936) has become a classic work. Once Hitler assumed power in 1933 the situation for Jews deteriorated rapidly. Psychoanalysts, many of whom were of Jewish origin, fled Germany, settling mostly in England and the US. Among them were Sandor Rado, founder of the Columbia Psychoanalytic Institute; Ernst Simmel, director of the Los Angeles Psychoanalytic Association; Edith Jacobson, a major theoretician who came to New York; Helene Deutsch, who wrote extensively on female psychology and on the “as-if character”; and Franz Alexander, who, after emigrating from Budapest to Chicago, wrote on psychosomatic medicine and also on the history of psychiatry. Alexander’s interest in finding correlations between certain somatic diseases and their presumed psychological precursors inspired Flanders Dunbar (and in Argentina, Angel Garma) to look for such patterns in conditions like ulcer, colitis, and asthma. Gastric ulcer, it was thought, occurred in persons who had introjected a demanding, hypercritical mother (who literally gnawed at one’s insides). It remained for Arthur Mirsky to show how simplistic such theories were. He postulated that, in the case of ulcer, hereditary gastric hypersecretion of pepsinogen was the more valid causative factor, supplemented by that of J. Papez on the limbic system, helping to put psychosomatic medicine on a firmer footing by showing a link between emotional and physiological states.

Eliot Slater in England found a monozygotic concordance rate of 86%. Later estimates have been lower (in the range of 40%), and the impression is that Kallmann was studying a group of particularly severely ill schizophrenic patients for whom the higher, but not truly representative, figure might have been justified.

The heritability factor in schizophrenia was revised upward in strength by Franz Kallmann, who estimated a monozygotic concordance at 86%. The US physiologist Walter Cannon (1881–1945) demonstrated the effects of intense emotional states—rage and fear—on the endocrine system, specifically that under severe stress the adrenal glands become activated. His work supplemented that of J. Papez on the limbic system, helping to put psychosomatic medicine on a firmer footing by showing a link between emotional and physiological states.

In 1935 Leo Kanner published the first textbook on child psychiatry in English. Kanner is also known for his theory that childhood autism, with its aloofness and uncommunicativeness, resulted from maternal “coldness.” It happened that the first cases he confronted were the children of women...
with PhDs in his own department. He assumed the mothers, being bright and career oriented, were somehow aloof from their children. In fact, they were quite devoted mothers; subsequent study showed that autism was the expression of biological factors (as was recognized by Lauretta Bender) and had nothing to do with cold mothers. A little later, mothers would come under fire again, as “schizophrenogenic” mothers who create schizophrenia by giving their children double messages. This equally specious theory nevertheless dominated the field until the 1970s and unnecessarily stigmatized many mothers of schizophrenic children. It was not long after Kanner’s book that the Viennese physician Hans Asperger published a paper in 1944, describing several children with an autistic-like syndrome, consisting of normal intelligence, but marked deficiencies in social and communication skills, failure to develop peer relationships, and often a preoccupation with restricted patterns of interest. Fifty years were to elapse before the syndrome was included, as an autistic-spectrum disorder, in DSM-IV-TR.

W.H. Sheldon continued the work of Kretschmer on correlations between body type and psychological type. He depicted three extremes of habitus: the (thin) ectomorph, the (fat) endomorph, and the (muscular, beefy) mesomorph. Sheldon concluded that schizophrenic patients were often ectomorphic and delinquents or gynandromorphic (having features of both sexes). In 1955 it was revealed that Sheldon made thousands of nude photographs of first-year college students. Some of these men and women went on to achieve great prominence. The negatives were traced—and shredded—along with Sheldon’s not totally incorrect but much overblown theory.

In 1948 Alfred Kinsey published his large-scale survey of the sexual habits and practices of US men, showing, among other things, that about 6% of men were fixedly homosexual. Although the study was not representative of the population and was methodologically flawed, it provided figures that were more realistic than were the assumptions held by the public beforehand.

David Wechsler, at New York’s Bellevue Hospital, developed an intelligence test (the Wechsler–Bellevue IQ test) considered more reliable than the earlier Binet–Simon test. Hans Eysenck in England created a system for evaluating personality based on three broad factors: neuroticism, extraversion, and psychoticism. The factors are used dimensionally; each person is assessed as belonging somewhere along these three axes, according to their responses to a standardized questionnaire.

In Switzerland, Jean Piaget made important contributions throughout the 1940s and 1950s to our understanding of normal intellectual development, outlining four phases of increasingly sophisticated thought processes in children. The progression Piaget outlined went from a sensory–motor stage (in which a child learns about surrounding space), through stages in which verbal symbols are learned and objects become classified according to similarities, to a stage of formal operations (in early adolescence) in which adult logic is utilized.

What is probably the most widely utilized test of personality, the Minnesota Multiphasic Personality Inventory, was developed by S.R. Hathaway and J.C. McKinley in 1940. This self-report instrument, with its 10-dimensional scales, generates a profile covering all major aspects of personality, with abnormalities emerging as high points on one or more of the scales.

Among psychoanalysts, interest in borderline conditions was growing when it was noticed that certain patients, although considered amenable to analytical treatment at first, failed to improve no matter how prolonged the analysis. Adolph Stern gave a workable, if loose, definition of the term borderline in 1938 (relying on such attributes as inability to withstand ordinary stresses and paranoid mechanisms). Melitta Schmideberg (the daughter of Melanie Klein) characterized these patients as stably unstable, referring to their ego weakness and to the predictable quality that their lives always seemed to be in a state of crisis. Borderline, for the analysts of this generation, meant two things: on the border between analyzability and nonanalyzability and also in the borderland between normality and schizophrenia (in the broad, Bleulerian way this was defined in that era). Meanwhile the Scottish analyst W. Ronald Fairbairn was proposing a modification of Freud’s instinct-based psychology with one based on object relations. The latter focused on the early mother–infant bond and its abnormalities rather than on the triangular oedipal situation and thus had greater explanatory power vis-à-vis borderline patients (whose primitive mental mechanisms bespoke an earlier set of abnormalities). Wilfred Bion (1897–1979), a Kleinian analyst, evolved a theory of group function, based on his experience with soldiers in two world wars, that underlined the importance of three basic assumptions—dependency, fight–flight, and coupling—that tend to dominate the reactions of people in groups (whether in small groups or in society at large).

In the realm of clinical neuroscience, the Portuguese neurologist Egaz Moniz (1874–1955) achieved fame through his development of lobotomy, the inspiration for which came from his belief that obsessive and melancholic patients suffered from recurring thoughts that might reflect the presence of reverberating circuits in the frontal lobe centers for consciousness. Lobotomy, by interrupting these pathways, ought to bring relief. Moniz used the procedure for schizophrenic patients as well. Although lobotomy has fallen out of favor (except in the cases of intractable obsessive–compulsive disorder), its initial apparent success was enough to earn Moniz a Nobel Prize. Less drastic measures for dealing with schizophrenic patients in this prephenothiazine era would include the extremely confrontational brand of psychoanalysis advocated by John Rosen. His Direct Analysis (1947) relied on blunt, repugnant interpretations (“What you really want is to suck your father’s dick!”) geared to jangle the patient out of backward torpor into greater perkiness and activity (which unfortunately wore off after a few weeks). Far more effective and humane were the techniques developed by Frieda Fromm-Reichmann, the much admired analyst at Chesnut Lodge near Baltimore, who was the beloved therapist of Hannah Green, author of I Never Promised You a Rose Garden. Fromm-Reichmann wrote her Principles of Intensive Psychotherapy, containing sound advice for the humanistic interpersonal approach to working with schizophrenic patients, including advice on how to work productively with the inevitable countertransference feelings elicited by extremely ill patients.

In biological psychiatry a great advance in the late 1940s was the discovery by the Australian researcher J.F.J. Cade of the calming effects of lithium salts. Mogens
Schou in Denmark and Ronald Fieve in New York pioneered the use of lithium for manic-depressive psychosis. Great advances were made in neural science by John Eccles, who probed single neurons with microelectrodes to study synaptic transmission—which then enhanced our understanding of the interactions among the myriad neurons that make up the nervous systems, whether of the humble Aplysia (as studied later by Kandel and Schwartz [1985]) or of man. Eccles’ first major study, *The Neurophysiological Basis of Mind*, was published in 1953.

Contributors to child psychiatry in this era include Margaret Ribble, who observed the destructive effects on infants of severe maternal neglect (the result might be a failure to thrive and wasting away, called marasmus), and David Levy, who wrote on the effects of maternal overprotectiveness (which might lead to excessive dependency). Adelaide Johnson published her landmark paper on the superego lacuna (1949) concerning juvenile delinquents who act out the gap, or lacuna, in the conscience of one or another parent.

Among the major accomplishments of the 1950s was the publication of the first edition of the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I). This represented the first attempt to provide operational definitions of the various mental disorders. Meyerian in its approach, DSM-I used the term reaction type—as in the diagnosis “schizophrenic reaction, paranoid type.” In New York, the Hungarian analyst Sándor Rado broke away from the New York Psychoanalytic Institute to found the Columbia Institute. Rado stressed the importance of better adaptation to one’s interpersonal world and also acknowledged the role of heredity in schizophrenia, proposing the term schizotype for the phenotype of the genetic factor(s) underlying the illness. Other influential analysts of this period include Robert Knight (for his work on borderline conditions), Edith Jacobson (a theoretician who also recognized the hereditary factor in certain cases of severe depression), Donald Winnicott (who described the transitional object), Annie Reich (former wife of Wilhelm Reich; she wrote extensively on countertransference), Heinz Hartmann (who pioneered ego psychology and the notion of a conflict-free ego sphere, embracing memory, language perception, and mathematical reasoning), and Eric Homburger Erikson (for his famous elucidation of life stages spanning not just the first 6 years of life but continuing throughout the life cycle). Nathan Ackerman applied analytical principles to the field of family therapy, of which he was essentially the founder.

Alcoholics Anonymous was founded in 1935 in Akron, Ohio, by “Bill” Wilson, but the organization’s growth did not reach worldwide proportions until the 1950s. By then the 12-step program, the model for all subsequent 12-step programs for combating other addictive behaviors was developed. Paul Freund of Beth Israel Hospital and M.S. Schwartz in Boston. Their publications led to greater efficacy on the part of hospital staff in dealing with narcissistically “entitled” and otherwise difficult patients.

For a time, the term pseudoneurotic schizophrenia, coined by Paul Hoch and Philip Polatin in New York, was a popular label for borderline patients who exhibited many different neurotic signs at once (obsessions, depression, phobia, chaotic sexuality). Most of these patients, it was later recognized, were not even in the penumbra of “true” schizophrenia but either suffered affective disorders or had been traumatized physically or sexually in their early years.

While these modest changes were taking place in the diagnosis and therapy of schizophrenia, a revolution was taking place in psychobiology. In 1951 Henri Laborit was using chlorpromazine in anesthesia and thought it might have applications in psychiatry. His French colleagues Joseph Hamon and, shortly thereafter, Jean Delay and Pierre Deniker used this agent successfully with psychotic patients. This was the birth of the tranquilizer era, to be followed almost immediately by the discovery of the monoamine oxidase and tricyclic antidepressants. I.J. Selikoff and J. Delay reported in 1952 on the use of iproniazid (Marsilid), R. Kuhn in 1957 on the use of imipramine (Tofranil). In 1960 L.H. Sternbach reported on the antianxiety properties of chlordiazepoxide (Librium). Methylphenidate (Ritalin) was found to be useful for children with attention-deficit/hyperactivity disorder and was studied extensively by Paul Wender. Ironically, the era of effective and specific medications for most of the severe psychiatric disorders was also the era of inappropriate experimentation with “model psychotics” drugs like lysergic acid diethylamide and with rampant abuse of illicit psychoactive agents like marijuana, methamphetamine (Methedrine), cocaine, and peyote, resulting in a worldwide plague that has not abated. Psychiatrists have had to familiarize themselves with the diagnosis and treatment of the self-induced paranoid and other psychoses, along with the conventional, idiopathic psychoses.

In the forensic area Hervey Cleckley gave a detailed picture of the psychopath, in the modern sense of the glib, remorseless antisocial person of the “con man” type, in his famous monograph *The Mask of Sanity* (1952). Cleckley devised a scale for diagnosing psychopathy, which was revised in the 1980s by Robert Hare of Vancouver and shown to have utility as a prognostic gauge in forensic work.

**Advances in the 1960s**

In the US and in many Western countries, the 1960s were characterized by what Christopher Lasch called the culture of narcissism. Development of better contraceptive devices (the “pill”) contributed to greater freedom for women, including the freedom to have fewer children and to pursue a career. The divorce rate increased steeply, leading to a destabilization of family life and the customary supports for children and adolescents. These changes in turn contributed to a heightening of the suicide rate, especially in young men, such that the high-risk age for suicide, which used to be in the sixth decade of life, is now in the third decade.

The improvements in psychopharmacology during the 1950s led to massive deinstitutionalization of the psychiatric hospitals, especially in the US—a mixed blessing, because many mental patients were now able to live extramurally and even take their place in the work sphere, but the still chronically (although now less floridly delusional) ill often drifted into homelessness.

In psychoanalysis the British Independent Group (Michael Balint, Donald Winnicott, Charles Rycroft) studied the object-relational abnormalities in borderline patients.
John Frosch in New York concentrated on the abnormalities in the sense, feeling, and testing of reality in patients with a psychotic character (similar to the borderline). Otto Kernberg, then director at the Menninger Clinic, published his landmark analysis (1967) of borderline personality organization, as a level of function between the neurotic and psychotic levels and characterized by an enfeebled identity sense yet with adequate reality-testing capacity. His recommendations for the treatment of borderline patients centered on the integration of their tendency toward splitting (seeing themselves and others as alternately all good and all bad). In London, Joseph Sandler, a major analytical theoretician, clarified diagnostic issues relevant to obsessive disorders, showing that there were two distinct entities: the characterological obsessive (similar to the current obsessive personality disorder) and the true obsessional picture (our obsessive-compulsive disorder).

The second edition of DSM was published in 1968, and its contents were brought more in line with the British and continental International Classification of Diseases by way of enhancing international communication and research. The sheer volume of knowledge in the various psychiatric subspecialties had by now increased to the point at which no one or two psychiatrists could write a complete textbook, derived solely from their areas of expertise. Lawrence Kolb in the US, D.K. Henderson and R.D. Gillespie in England, and Nils Retterstol in Norway were among the last to offer such works. From now on multiauthored texts guided by a few editors became the norm: Arieti’s Handbook, Kaplan and Sadock's textbook, and later those of Robert Michels or of Stuart Yudofsky or the current one, edited by Tasman, Kay, Lieberman, First and Maj.

The 1960s also marked the transition between old conceptions about homosexuality, such as espoused by Irving Bieber, and newer theories, championed by Robert Spitzer. Bieber saw homosexuality as an illness (the prevailing view among psychoanalysts), engendered by aloof fathers and seductive, overinvolved mothers. Spitzer, Richard Friedman, and others argued that homosexuality represented simply a different sexual orientation within our species, determined largely on biological and constitutional grounds, not a pathological condition caused by this or that family pattern. The latter view prevailed (although politically correct, it also happened to be scientifically correct) and led to the demedicalization of homosexuality (i.e., it was no longer listed in DSM as a pathological condition). Meantime, the tendency of some heterosexual men with sexual inadequacies to fear being homosexual was described by Lionel Ovesey, under the heading “pseudohomosexuality.”

Behavioral therapy was gaining ground in the 1960s, thanks to the research of Isaac Marks in England and Ben Wolpe in the US. Aaron Beck in Philadelphia was another pioneer in this field. All made major contributions to the therapy of phobic conditions, anxiety disorders, and depression, showing that the clinical efficacy was as great as and often greater than that of psychoanalysis and took less time and expense.

The intensive, analytically oriented psychotherapy of schizophrenia, honed by the skills of Harold Searles, Silvano Arieti, Marguerite Sechehaye in Zurich, Racamier in Paris, and Margaret Little and Herbert Rosenfeld in England, was now challenged by a new generation of investigators who saw no superiority in outcome of this method, compared with supportive therapy plus the neuroleptic drugs. At the vanguard of the new movement was Philip May in California, whose 1969 book, despite its shortcomings (May's patients were poorly educated and were treated only by residents in training over just a few months rather than years), set the therapy of schizophrenia on a new track. Henceforth, the emphasis would be on medications, rehabilitative measures, and social skills training.

Spurred by the discovery of the rapid eye movement phase of sleep and its connection to dreaming (by E. Aserinsky and N. Kleitman in 1953), researchers (such as Howard Roffwarg, W.C. Dement, and Ernest Hartmann) began to reappraise Freudian concepts of dream function. It seemed closer to the truth to think of dreams as a problem-solving mechanism (engrafted onto a common mammalian phenomenon), rather than as the “guardian of sleep” or “expression of wish fulfillment” as Freud had postulated.

In the field of affective disorders, controversy continued over whether manic-depressive psychosis was one condition or an umbrella term for two. Jules Angst in Zurich and George Winokur and Paula Clayton in the US concluded that it made better sense to speak of two forms: bipolar and unipolar depressed. There is a greater tendency for ill relatives of bipolar individuals to have bipolar disorder and vice versa.

More sophisticated twin studies in the 1960s, especially by Einar Kringlen in Norway, pointed to a heritability figure for schizophrenia of about 40%. This is not to be interpreted as meaning that schizophrenia is genetically based in only 4 cases of 10, but rather that, as Lucille Erlenmeyer-Kimling in New York suggested, the idiopathic cases are always genetically based but the phenotype (the clinically obvious case) does not always develop, sometimes because of low genetic liability, favorable modifying influences, or other reasons.

Not all manic patients respond to lithium, so it was a pleasant discovery in the 1960s (once again by a French investigator, Lambert, with his colleagues, Carraz and Carbel [1966]) that valproic acid, ordinarily used as an anticonvulsant, also had antimanic properties.

Wigan’s hunch of the 1840s having been long forgotten, it was not until the 1960s that real progress was made in understanding the roles of the two cerebral hemispheres. Much of the work was done by R.W. Sperry, Michael Gazzaniga, and Joseph Bogen. Besides showing that the dominant hemisphere (usually the left) mediates sequential, logical thought and arithmetical reasoning and the nondominant visual-spatial tasks, comprehension of emotions, and jokes, this research also proved relevant to the problem of dyslexia. Some individuals with dyslexia, for example, were, as Martha Denckla observed, right handed and right footed but left eye dominant, and perhaps more vulnerable as a result to confusion in learning to read.

The barriers to recognition of physical and sexual abuse of children were finally breached in the 1960s. Arthur Green in New York and other physicians had the courage to follow up on their suspicions in the cities’ emergency departments and documented how often children’s burns and broken bones had been inflicted by their parents and caretakers. It became clear that incest was not something that happened now and again in Greek plays but happened here and often.
Solid epidemiological data on the topic were beginning to accumulate, although the best studies (such as that of Diana Russell in San Francisco) were not to be completed until the 1980s.

The characteristics of children and adolescents at high risk for schizophrenia and manic-depressive illness were mapped out by a number of researchers in the 1960s: Sarnoff Mednick, Seymour Kety, David Rosenthal, and Paul Wender, all relying on the Danish adoption records; L. Erlenmeyer-Kimling, concentrating on schizophrenia; and Ella Pozanansky, Dennis Cantwell, and Clarice Kestenbaum, concentrating on affective disorders. These studies helped identify the “soft” signs of the major conditions before they acquired their full form in adult life.

The displacements and losses suffered by millions of persons during World War II stimulated research on the effects of separation and death of loved ones on small children. Outstanding among these investigations were the works of John Bowlby in England, who identified three stages in the grief reaction: initial protest, despair, and finally detachment. The first volume of his trilogy, Attachment, Separation, and Loss, appeared in 1969.

Biologists such as Austria’s Konrad Lorenz and Irenäus Eibl-Eibesfeldt in Germany opened up a field of great relevance to psychiatry: ethology (the study of species, including our own). These investigators drew attention to the innate, preprogrammed patterns that underlay many of the approach–avoidance and sexual behaviors in animals and humans. Using motion photography, Nikolaas Tinbergen focused on human gestures, including the unconscious tendency of men to straighten their ties and pull in their stomachs when introduced to an attractive woman—apparently to create a more “masculine” image.

Inspired by emerging ethological data, Jane Sherfey reworked Freudian theory of male and female sexuality in her monumental integrative monograph of 1966. She argued that neither sex is programmed biologically for monogamous marital life; rather, our mating system (emphasizing monogamy, kinship ties, inheritance laws, and so forth) grew out of compelling survival needs as we ceased to be nomadic hunter–gatherers and developed agriculture and geographically stable communities.

Recent Trends
Progress in psychiatry has been so enormous in the past 25 years that it would be no exaggeration to say that more has been written, and more knowledge has been accumulated, during this period than in the preceding 2,500 years. This chapter is devoted to the history of psychiatry, yet history inevitably blends into current events seamlessly and without a clear boundary. For reasons of space and the past quarter-century has more the feel of current events than of history (at least to those old enough to have been in the field more than 25 years), it has been chosen to present, relative to this period, simply the highlights (Table 14–1). Table 14–1 lists some of the more important advances or trends, along with (where pertinent) the main authors or initiators of these developments. Before moving to these highlights, we must single out a most important highlight: the awarding of the Nobel Prize for medicine in 2000 to the Columbia University professor, Eric Kandel, for his work on memory mechanisms in humans as well as in other animals—the outgrowth of his research on the small invertebrate, Aplysia.

The exponential growth of new information in articles and books in our field, even since the last edition of Psychiatry in 2003, has meant that the path from “current events” to what feels like “history” is even shorter than it was from the first to the second edition.

Since the time when the second edition was in preparation, for example, the “atypical” antipsychotics, such as risperidone, olanzapine, aripiprazole, and their close cousins, have become “typical”; the older medications—chlorpromazine, haloperidol, fluphenazine, etc.—are either used less than before or else have fallen into desuetude. In the domain of bipolar illness, there is now an expanded array of antimanic medications, including lamotrigine, which has offered an effective alternative to lithium in the control especially of those bipolar persons prone to episodes of depression.

Thanks to the new and developing field of pharmacogenomics, we have begun to increase our understanding of the genetic variability to the efficacy and also to the toxicity of various psychopharmacological agents—a point made by Julie Johnson in the first issue of the American Journal of Pharmacogenomics (2001). From this research, it has been learned that there tend to be differential responses to lithium and neuroleptics in Asian-American, as compared with Caucasian patients. This may relate to differences in the activity of CYP2D6 and CYP2C enzymes in the two groups. Similarly, Black patients may require smaller doses of tricyclic and serotonin reuptake blocking antidepressants than would be needed in Caucasian patients, to achieve similar antidepressant responses. Further research concerning group differences may lead to better selection and dosages of psychotropic drugs at the onset of a condition, with less need than in the past for empirical, time-consuming trial-and-error choices.

In the field of personality disorders, many experts have drawn increasing attention to the need for adding a dimensional, as opposed to merely categorical, perspective to the array of disorders. John Livesley, John Oldham, Thomas Widiger, Robert Cloninger, among others, have championed this approach, and have devised new dimensional schemata for amplifying the next edition of the DSM in its section on personality. Perhaps this amounts to pouring old wine in new bottles, inasmuch as the MMPI devised by Hathaway and McKinley in 1940, and widely used ever since, embodies a dimensional view of personality, acknowledging that people each show varying degrees of the conventional and arbitrarily chosen “categories” of personality.

Very much in vogue over the past few years are elaborate manuals for different types of psychotherapy. Thus, Marsha Linehan and her colleagues have compiled a manual for the proper carrying out of dialectic behavior therapy (DBT); Kernberg, and his coworkers have published a manual of guidelines for conducting transferance-focused psychotherapy (TFP); Bateman and Fonagy have recently published (2004) an encyclopedic work on borderline personality disorder, containing within it a manual for their mentalization-based treatment for borderline patients. Arnold Winston and his colleagues (including Henry Pinasker, who had published a similar work in 1997) have written guidelines for supportive psychotherapy. Manuals of this sort have the advantage of contributing to

the standardization of therapeutic techniques. In addition they facilitate research (including randomized controlled studies of contrasting methods) concerning the effectiveness of the different approaches, in hopes of creating a generation of psychotherapies that are empirically supported and "evidence based" (a term also very much in vogue currently). The new emphasis is not without its downside. There is now a tendency to derogate the psychoanalytic therapies partly because, by their very nature, it is inherently difficult to compress them into the evidence-based mould—as has been pointed out by Nancy McWilliams 2004 in her excellent guide to psychoanalytic psychotherapy. But this does not invalidate the utility of the analytic therapies, given the well-trained therapist and the amenable patient. Perhaps there is an analogy to chess. There are well thought-out theories, some very definite don'ts and some highly recommendable do's in chess, but in between a nearly infinite sea of choices that cannot be reduced to a manual, no matter how lengthy. So it is with psychotherapy.

Many have argued for an eclectic approach to the therapy of the more severe personality disorders, even while acknowledging that one must be grounded in a particular method—before incorporating and utilizing other techniques as the occasion may demand. John Livesley and John Gunderson have espoused this position, as have Judd and McGlashan (2004) in their outstanding treatise on the therapy of borderline patients.

One of the goals of the various psychotherapeutic approaches to the treatment of personality disorders, especially that of borderline personality disorder (BPD), is to help the patient advance from a state of insecure attachment (with its various subtypes: entangled, disorganized, and dismissive) to a state of secure attachment. This emphasis on attachment type and level, which is noticeable in much of the recent literature on therapy, derives from increasing attention to the work of earlier investigators in this field: John Bowlby in the 1950s, Mary Ainsworth in her work on assessing infant attachment in the 1970s, Mary Main, who with her colleagues developed scales for the assessment of adult attachment types, and in the last few years, Otto Kernberg and Peter Fonagy in their works on the treatment of BPD. And Sonkin and Dutton 2003 have even shown how the psychology of attachment and its abnormalities can be made applicable to their work with assaultive men.

An emerging field whose research has contributed both to our understanding of personality and to the treatment of its disorders is evolutionary psychiatry. Prominent investigators in this area include the following: Richard Dawkins; Anthony Stevens and John Price; Jerome Barkow, Leda Cosmides, and John Tooby; Joseph LeDoux; Michael McGuire and Alfonso Troisi; John Cartwright and Nancy Etcoff. Whereas conventional psychiatry focuses on the abnormal aspects of personality, that is, the disorders of personality, evolutionary psychiatry focuses on the adaptive aspects of the different personality configurations. Seen in this light, the "disorders" can be understood as exaggerations of tendencies that in less intense form serve valuable purposes in a social species like ours. In what is termed the evolutionarily stable state, a community will be divided into certain proportions of leaders, followers, meticulous workers, unconventional

“creative” types, extraverts, introverts, persons susceptible of guilt, persons with few scruples, and the like. Take these various types toward their extreme and one sees the “disorders”: the hypomanic, the schizoid, the obsessive–compulsive, the hysteric, the depressive, the antisocial, and all the rest. From the standpoint of evolutionary “fitness” (which relates, not to the success of the individual, but to the number of offspring left in the next generation), it can be seen that certain antisocial men impregnate a number of women, whom they then abandon—but whose DNA is sent into the next generation—even if the negligent father is subsequently killed at an early age in a barroom brawl. Survival needs universal in our species are emphasized in evolutionary psychiatry, such as that of resource-holding power. This relates to the ability to accumulate and retain valuable goods and relationships that will guarantee the survival of the individual and his or her offspring. Nancy Etcoff 2000 has written on the way in which feminine beauty serves this need: beauty, in evolutionary language, equates with the visual cues that signify symmetry (equated in turn with physical health) and fertility (youthful appearance, waist-to-hip circumference of about 0.7, dimpled cheeks that signal puberty). The sexual attractiveness associated with these features conduce to successful reproduction, hence evolutionary fitness.

Considerable strides have been made in the past few years in study of the human brain via magnetic resonance imaging and related techniques. This is true even in the area of personality disorder, where Bremner has recently shown (2005) abnormalities in borderline patients. In women with borderline personality who had histories of early abuse, for example, decreased function was observed in the anterior cingulate and temporal cortex. Diminished anterior cingulate function, as Larry Siever’s work suggests, is associated with a poorer “braking mechanism” giving rise to exaggerated reactions of fear, panic, or rage in response to key interpersonal stresses. The recent overview on neuroimaging by Dougherty et al. 2004 is a rich source of information about brain abnormalities in schizophrenia (viz., ventricular enlargement, medial temporal abnormalities, etc.), post-traumatic stress disorder (PTSD), and various cognitive disorders, including Alzheimer’s disease.

Apropos Alzheimer’s disease, recent research has identified a gene, in addition to the earlier identified Apolipoprotein-E4 gene, that is associated with the commoner, late-onset (after age 65) form of the disease. This gene, called SORL1, has been noted with greater than expected frequency in certain ethnic groups. Meantime, a chemical marker called FDDNP, when injected intravenously during positron emission tomography (PET) has been shown helpful in detecting the plaque and tangle deposits associated with the disease—when it is still in the subclinical stage. The discovery of more such genes that may be involved with Alzheimer’s lends some hope of better diagnostic tests for spotting those at risk, and of better drugs to combat or forestall its devastating effects.

There has been renewed interest in the topic of empathy, particularly in relation to gender differences in brain structure and function. Simon Baron-Cohen and his colleagues, in a recent book (2003), entered this controversial area, making a number of interesting observations. Female-type brains appear, on average, better at empathizing and communicating; male-type brains, better at understanding and building systems. Asperger’s syndrome, viewed in this context, emerges as an extreme type of the male brain: those who exemplify the syndrome seem unusually good at analyzing complex systems, and uncannily handicapped at grasping emotions and at relating to the emotional nuances of those in their midst. At the end of the book is an empathy scale composed of 36 faces, each with a different emotional expression: the reader must choose among four possible descriptive adjectives. In general, women are shown to perform better in this test than men.

In the forensic arena research in the last few years, much attention has been devoted to the neurobiology of violence. Several excellent texts are available (Niehoff 1998, Volavka 2002). The focus in many related articles is on neurophysiological abnormalities in criminal psychopaths, about which Adrian Raine has been an important contributor (Raine et al. 2003, Yang et al. 2005). Psychopathy (especially in persons “unsuccessful”—in that they were caught) has been associated with diminished prefrontal gray matter. Psychopaths tend also to show an increase in callosal white matter—which Raine suggested might underlie atypical neurodevelopmental processes in psychopathy, including the affective and interpersonal deficits associated with this personality type. Decreased reactivity has also been noted in psychopaths during evoked potential studies of reactions to highly emotional words, which may account for the glibness of speech and facility in lying that are prominent characteristics of the psychopath. A crime that has been on the rise in recent years is that of stalking, whether of romantic partners (actual or imagined), celebrities, or persons in the workplace who have disappointed or dismissed an employee. Specialists who have written extensively on the taxonomy, nosology, treatment, and legal implications of stalking include Paul Mullen and Reid Meloy; some of their contributions are included in the compendium edited by Boon and Sheridan 2002. Stalking and attachment are interrelated topics, inasmuch as the stalkers are pathologically unable to detach themselves from the objects of their relentless pursuit. In an interesting footnote to the subject of homicide, including the murders of teachers and fellow students by adolescent school-shooters, and also suicide over the entire age range, a recent study from the Harvard School of Public Health has demonstrated that the states with the highest rates of household firearms (viz., Wyoming, Alaska, Montana) have significantly higher homicide rates than is noted in states, such as Massachusetts, where the gun ownership rate is at the lowest level for the US. This was particularly true of women who were killed by guns, since they are killed usually by current or former boyfriends or spouses, using guns that were already in the home.

Conclusion

It is difficult to tell what age one has been living in until it has passed. We can easily see now the cultural influences that shaped Freud’s thinking—about the roles of fathers and mothers, about women’s “masochism,” about “unconscious homosexual strivings” in paranoia—because we have the distance of a century to give us perspective. What about trends now? Certainly we can say that this is a time when, thanks in part to the computer, symptom-specific drugs, neuroimaging techniques, and rigorous statistical methodology, our interests have shifted toward the biological and...
away from the individual. Psychiatrists often rely more on fluoxetine (Prozac) than on the spoken word. We have seen that a similar shift occurred in the 19th century.

There is no question that past generations of psychiatrists have witnessed exciting discoveries. (See Figures 14–9 and 14–10.) Some have been alluded to in Table 14–1; brain imaging has shown loss of tissue in associational areas of the cortex (hypofrontality) in chronic schizophrenia. abnormalities in basal ganglion pathways have been outlined in obsessive–compulsive disorder, abnormalities in autonomic nervous system function, and in “empathy centers” have been proposed as the key to psychopathic behavior, and Bessel van der Kolk’s neuroimaging studies of traumatized persons (in whom Broca’s language area does not “light up” when they concentrate on a painful memory) help explain the failure, in many cases of posttraumatic stress disorder, to remember in words. All these are a tribute to the triumph of biological psychiatry in the late 20th century.

While this is happening, we hear even so biologically oriented a researcher as Robert Cloninger speak of having identified yet another key variable in personality: self-transcendence. Van der Kolk mentions, as a soft sign in posttraumatic stress disorder, loss of faith in the future and of trust in other people. These qualities are related to our humanness and to the unique qualities of individuals. This is what we do not hear when we listen only to Prozac. In a parallel fashion, a number of books have appeared on our moral sense and its biological, evolutionary roots: James Q. Wilson’s The Moral Sense (1993), Matt Ridley’s The Red Queen: Sex and the Evolution of Human Nature (1993), and Robert Wright’s The Moral Animal (1993). Wilson reminds us that human society is held together by fine wires of sympathy, fairness, self-control, and duty, built into us through evolution because of their survival value in a communal animal. Psychiatry had for too long put these issues on the back burner. And our enthrallment with biology has begun to put human individuals, our one-at-a-time psychiatric patients, on the back burner. It should not surprise us, then, that in the current century, alongside the breathtaking strides of biological psychiatry—for they will continue—a new Ideler or Freud will emerge, redirecting our attention to the individual and to some new kind of verbal psychotherapy keyed to the needs and sufferings of 21st-century men and women.

Figure 14–9 Timeline 1500–1900 (Source: Courtesy of WW Norton & Company: excerpt from Healing the Mind—A History of Psychiatry from Antiquity to the Present by Michael H. Stone, M.D. Copyright 1997 Michael H. Stone, M.D., pp 435–438.)
### Chronology of Historical Events and Persons: 15th–20th Centuries

#### 15th–16th Centuries

**1445** Gutenberg invents the printing press.

**1453** Constantinople falls to Mehmet II.

**1492** Columbus discovers America.

The beginning of the Spanish Inquisition; dominated by persecution, burnings, or expulsion of Jews and Moors.

**1517** Luther (1483–1546) posts his 95 theses at Wittenberg, demanding discussion about the abuses of indulgences.

**1520** Luther’s efforts at reformation begin to succeed; Philip Melanchthon offers formulation of Luther’s doctrines.

**1521** Lutherans in the Netherlands are persecuted by Charles V; heretics are burned in Brussels.

**1531** In England, King Henry VIII (1509–1547) is recognized as head of the Anglican Church.

**1534** Ignatius Loyola (1491–1556) founds the Jesuit order.

**1535** English clergy deny authority of the Pope, but Sir Thomas More refuses to acknowledge the supremacy of the king and is executed for treason.

**1536** Calvin (1509–1564) promulgates his Protestant doctrine in predestination to either salvation or damnation.

**1540** Andreas Vesalius, Flemish anatomist, presents drawings of the anatomy of the human body.

**1543** Copernicus, promulgator of heliocentrism, dies.

**1546** Holy Roman Emperor Charles V fails to win back Metz and Verdun from France and abdicates; this contributes to a gain in power for the nation state and to forfeiture of the dream of a universal Catholic empire.

**1558** Birth of Queen Elizabeth (d. 1603), who retains concept of royal supremacy over the Church.

**1559** Geneva becomes center of Protestant world; Calvinsim spreads to countries outside Switzerland.

**1556** Birth of Galileo.

**1562** Hugenot wars erupt in France; many Hugenots leave France following their defeat in 1593 by Cardinal Richelieu.

**1566** Calvinism becomes official church in the Netherlands.

**1572** Twenty thousand Hugenots are massacred in France.

**1588** Birth of English philosopher John Locke (d. 1704), a senior figure in British empiricism who postulates that experience (ideas of sensation and reflection) form the basis of understanding. **Some ideas (the “primary qualities”), however, come from an “all-knowing God.”** Locke believes that religion and morality are open to demonstration and proof, as is mathematics.

**1596** Birth of Spinoza, whose concept of oneness of thought and existence helps pave the way for the Enlightenment.
Chronology of Historical Events and Persons: 15th–20th Centuries  Continued

**1649** Charles I of England is beheaded; Cromwell assumes power; Charles II goes into exile.

**1661** The monarchy in England is restored and Charles II is crowned as king.

**1665** Newton invents the Calculus (as does Leibniz independently in 1672). Robert Hooke’s book on microscopy is published.

**1690** John Locke’s “An Essay Concerning Human Understanding” is published.

**1694** Birth of Voltaire (d. 1778), French philosopher/essayist, who argued against the Church and the notion of faith.

**18th Century**

**1704** Isaac Newton’s “Opticks” demonstrates wave aspect of light.

**1710** George Berkeley’s essay, “A Treatise Concerning the Principles of Human Knowledge,” is published.

**1711** Birth of David Hume, English skeptical philosopher, whose tendency to doubt all “certain” knowledge challenges and limits the assertions of the Enlightenment: Man is a tabula rasa at birth, upon whom experience impresses its symbols.

**1712** Birth of Rousseau, Swiss/French philosopher, whose views that man was good by nature—corrupted because he does not allow himself to be guided by his feelings—places him in the next movement following the Enlightenment.

**1714** John Locke’s *An Essay Concerning Human Understanding* is published.

**1724** Birth of Immanuel Kant in Prussia.

**1728** Death of Cotton Mather, Massachusetts witch hunter.

**1729** Death of German/Jewish philosopher, Moses Mendelssohn, grandfather of the composer; around this time there is greater tolerance in Germany toward the Jews.

**1733** Birth of German physician and hypnotist, Anton Mesmer.

**1735** Linnaeus, Swedish botanist, publishes his taxonomy of organic life.

**1739** Hume’s “A Treatise of Human Nature” is published.

**1745** Birth of Benjamin Rush, Philadelphia physician/alienist.

**1754** Birth of Hegel in Prussia.

In Kant’s inaugural dissertation he asserts that we have a priori knowledge of space and time only because they are forms imposed by our own subjective experience, which also determines the schema of space and time, and gives rise to the distinction between things as they are in themselves and things as they are perceived by us, and to the distinction between experience and thought.

**1770s** Steam power, civil liberty, and free trade give rise to the Industrial Revolution, first in England, thence throughout the world.

**1771** Galvani discovers electrical nature of nerve impulses.

**1774** Goethe’s publication of *The Sorrows of Young Werther* marks the beginning of German Romanticism and emphasis on the individual and the emotions (the novel also sets off a wave of suicides in Europe).

**1775** Digitalis used by Withering for “dropsy.”

**1776** James Watt’s invention of the steam engine.

**1781** Kant’s Critique of Pure Reason is published, whose ethic is based on the search for a supreme principle of morality, a “categorical imperative” (in practice, similar to the Golden Rule). Kant’s *idealist* represents a break with empiricism, whereby knowledge is tied to experience.

**1784** Louis XVI commissions Lavoisier, Guillotin, Benjamin Franklin, and others to examine the merits of Mesmer’s claims.

**1789** The storming of the Bastille and beginning of the French Revolution.

**1790** Jews in France are granted civil liberties.

**1796** English physician William Jenner synthesizes a vaccine against smallpox.

**19th Century**

**1800** Napoleon becomes First Consul and commissions a civil code to be drawn up: the “Napoleonic code.”

**1804** Napoleon is proclaimed emperor of France.

**1807** Robert Fulton’s paddle steamer navigates the Hudson River. Publication of Hegel’s *Phenomenology of the Mind*. Arguably the most prominent philosopher in 19th-century Germany, influencing Marx and Engels, Hegel views history as progress toward freedom, conceived not as mere license, but as living self-consciously in a rationally organized community via the consent of the rational conscience of its members. Hegel writes in the spirit of German Romanticism, admiring skepticism, with its respect for freedom and reason (leading to the point where the “mind knows itself”). Hegel’s prescription for reaching the ultimate goal is the *dialectic*: using reason to overcome the contradiction between thesis and antithesis, via finding the proper synthesis, again and again, until perfection is reached.

</table>
Chronology of Historical Events and Persons: 15th–20th Centuries  
Continued

1869  Parliamentarian system is reintroduced in France.
John Stuart Mill’s *The Subjection of Women* and Francis Galton’s *Hereditary Genius* are published.

1870  Franco–Prussian war erupts, ending the next year with France ceding Alsace-Lorraine to Germany. *Kulturkampf* against the Catholic Church in Prussia; doctrine of papal infallibility is enunciated at First Vatican Council.

1871  Darwin’s *The Descent of Man* is published.

1873  A republic is proclaimed in Spain. Development of color photography.

Wundt’s *Physiological Psychology* is published.

1875  Alexander Graham Bell invents the telephone.

1876  Thomas Edison invents the phonograph.

1877  Victor Emmanuel, king of united Italy, dies, succeeded by Humberto I. In Germany, historian Treitschke begins radical anti-Semitic movement.

1878  Birth of Albert Einstein.

1880  Electric lights invented by Thomas Edison and Joseph Swan.

1881  Pogroms unleashed in Russia; many Jews emigrate to Western Europe and United States.

1882  Joseph Breuer, Viennese physician, uses hypnosis to treat hysteria.

1883  Nietzsche’s *Thus Spake Zarathustra* is published. Nietzsche describes a “will to power” as the prime moving force in human nature; failure to win power breeds resentment. The so-called *Übermensch* (the “Over-Man”) escapes this resentment not by bullying (as the Nazis supposed, later on) but by mastering his passions and embellishing his character with creativity. Also skeptical about objective notions of truth or fact and the supremacy of reason, Nietzsche’s views were a forerunner of “postmodern” deconstruction preference for a large variety of interpretations of a text, etc.

1885  Karl Benz, German inventor, invents the motor car.

1886  Krafft-Ebing’s *Psychopathia Sexualis* is published.

1888  “Jack the Ripper” murders six prostitutes in London; he is never identified or captured.

1890  Bismarck is dismissed by Wilhelm II of unified Germany.

1893  Henry Ford builds his first car.

Breuer and Freud’s first paper on hysteria treated by psychoanalysis is published.

1894  Auguste Marie Louis Lumière, French inventor, builds first cinematograph, precursor of movies.

John Dewey becomes chairman of University of Chicago department of philosophy and psychology. A pragmatist, he opposes the formal, rigid educational practices of his time, arguing that the child is an active, inquisitive creature, whose education must be fostered by experience, supplemented by knowledge and acquisition of skills. Enquiry is seen as a self-corrective process by Dewey.

1895  First wave of Turkish massacres of Armenians, culminating in mass murder of Armenians in 1915.

Discovery of X-rays by German physicist Wilhelm Roentgen.

Persecution of Oscar Wilde for his homosexuality.

1896  French physicist Alexandre Becquerel discovers radioactivity, followed by the Curie’s discovery of radium and polonium (1898).

1897  English psychologist Havelock Ellis’ *Studies in the Psychology of Sex* is published.

1899  Freud’s *Interpretation of Dreams* is published (though with publication date of 1900).

20th Century

1900  Death of Nietzsche.

Max Planck formulates quantum theory of physics in Germany.

1901  The “Edwardian Era” begins as Edward VII succeeds Victoria. Italian physicist Guglielmo Marconi transmits messages via radio.

1903  The Wright brothers invent and fly an airplane.

1904  Marie Curie’s *Research on Radioactive Substances* is published.

The Russo–Japanese war erupts.

1905  First workers’ soviet formed in St. Petersburg, partly in reaction to Russia’s loss in the war with Japan; sailors mutiny on the battleship Potemkin.

Albert Einstein formulates his “Special Theory of Relativity” and the photon theory of light.

Birth of Jean Paul Sartre, existential novelist and philosopher. Opposing psychoanalysis, Sartre argues against determinism and the notion of unconscious motivation, and in favor of “free will.” Only humankind, with its capacity for subjectivity, has the possibility of stepping outside the chain of causality and of exercising freedom of choice.
Chronology of Historical Events and Persons: 15th–20th Centuries  Continued

1907  William James’ Pragmatism in published, built upon the work of Charles Pierce (1839–1914). James’ treatise denies the possibility of absolute truth in an ever-changing universe, absolute moral standards must be replaced by a system of values, taking into consideration the vicissitudes of human experience.

Women are given suffrage in Austria.

1909  Freud and Jung lecture in the US at Clark University.

Women are admitted to German universities.

1911  Fall of the Manchu dynasty in China; a republic is proclaimed.

1912  The Titanic sinks on her maiden voyage.

Scottish physicist Charles Wilson detects electrons and protons in cloud chamber.

1913  Birth of Albert Camus, existential novelist, who emphasizes the individual, the experience of choice, the inability to comprehend the universe, with a consequent sense of the “absurdity of life.”

Publication of Edmund Husserl’s Phenomenology and Karl Jaspers’ General Psychopathology.

1914  Outbreak of World War I.

English philosopher/mathematician Bertrand Russell’s Our Knowledge of the External World is published.

1915  Einstein postulates his “General Theory of Relativity.”

Margaret Sanger is jailed for writing Family Limitation, the first book on birth control (the following year she opens the first birth control clinic).

1916  The Russian Revolution erupts; Lenin becomes chief commissar.

1917  Influenza pandemic.

World population is recorded at 1.8 billion; USA, 105 million.

Rorschach develops inkblot test in psychology.

1921  Bertrand Russell’s Analysis of Mind and Wittgenstein’s Tractatus Logico-Philosophicus are published.

Death of Prince Peter Kropotkin, Russian philosopher, who asserted that humans are social creatures who flourish best in small communities; he disapproved of the centralized state with its use of coercion.

American biologist Thomas Hunt Morgan presents his chromosome theory of heredity.

1923  Death of Lenin; Stalin assumes power in USSR.

Publication of German Protestant theologian Karl Barth’s The World of God and the World of Man assert that we cannot attain knowledge of God via use of reason; unlike traditional Calvinists, he did not believe in the possibility of redemption for everyone.

1925  Scottish inventor John L. Baird transmits images via television.

Physicists Werner Heisenberg and Neils Bohr develop quantum mechanics at atomic level.

Tennessee forbids sex education in schools; also in Tennessee, John Scopes is narrowly acquitted for teaching evolution in a public school.

1926  Hitlerjugend founded in Germany.

Joseph Goebbels appointed by Hitler as Gauleiter in Berlin.

Leon Trotsky expelled from Moscow.

Hirohito becomes emperor in Japan.

1927  Russian physiologist Ivan Pavlov’s Conditional Reflexes is published.

Publication of Being and Time by German existentialist philosopher Martin Heidegger, who urges return to “authentic communion with independent nature”; he equates “being” with people’s consciousness of their place in the world (their Dasein). His image was ultimately sullied by his championing of Nazi Germany.

1928  Scottish bacteriologist Alexander Fleming discovers penicillin.

1929  World economic crisis ushered in by Wall Street stock market “crash” on October 28th.

1932  Hitler gaining power in Germany; Nazis achieve plurality in the Reichstag.

Publication of French philosopher Henri Bergson’s The Two Sources of Morality and Religion. An evolutionist who was hostile to materialism, Bergson views evolution not in Darwinian terms as driven by natural selection, but as propelled by a “creative life force” (the élan vital). Modern developments in evolution and neuroscience have discredited his views.

Nobel prizes awarded to Edgar Adrian and Sir Charles Scott Sherrington for their work on neurons.

1933  Outbreak of World War II; flight of many Jews, including a large number of psychoanalysts, to England and the US.
### Chronology of Historical Events and Persons: 15th–20th Centuries

**1942**
First automatic computer is constructed in the US.  
Publication of German philosopher Hans Reichenbach’s *Philosophic Foundations of Quantum Mechanics*, emphasizing considerations of probability rather than reductionism.

**1943**
Publication of French philosopher and novelist Jean Paul Sartre’s *Being and Nothingness*, focusing on the structure of consciousness and emphasizing the capacity for choice as the essential feature of human nature. By virtue of our consciousness and intentionality, we are responsible for our choices.

**1945**
World War II ends with the defeat of Germany in May and Japan in August—the latter following the atomic bombing of Hiroshima and Nagasaki, ushering in the Atomic Age; discovery of the death camps in Poland and the full extent of the Holocaust: 8–10 million killed, including 6 million Jews from all over Europe.

Approximate beginning of steep rise in world population.

**1947**
Culmination of “nonviolent” movement in independence of India.

**1949**
Communist takeover in China under Mao Zedong.

**1950**
Publication of American anthropologist Margaret Mead’s *Social Anthropology*.

**1951**
Death of Wittgenstein, whose logical-positivist position opposes scientific (especially Freudian) reductionism and the then more accepted theory of consciousness as a manifestation of atomic and evolutionary processes peculiar to organisms with highly developed nervous systems.

**1953**
Death of Stalin and his succession by Krushchev in USSR; coronation of Queen Elizabeth II in England.

**1956**
Publication of British philosopher Alfred Ayer’s *The Problem of Knowledge*, whose *Language, Truth and Logic* appeared in 1936, combining empiricism and the focus on logic as espoused by Bertrand Russell.

**1957**
Death of John von Neumann, US mathematician (noted for his theory of games and decision-making), whose work led to construction of newer, more powerful computers.

**1960**
American scientists develop the laser.

**1960s**
Beginning of dramatic increase in abuse of illicit drugs in the US and Western Europe.

**1961**
First US space flight.

**1962**
Nobel Prizes awarded to James Watson and Francis Crick for discovery of the molecular structure of DNA.

**1963**
Assassination of President John F. Kennedy.

**1964**
US enters the Vietnam war (lasts until 1975).

**1965**
Social theorist Herbert Marcuse’s book *One Dimensional Man* becomes the Bible of radical students.

**1968**
Period of student rebellions in the US and Western Europe; rise of the feminist movement; violent crime increases more than 50% since 1960.

**1969**
First manned landing on the moon.

**1973**
Women’s rights advanced by Supreme Court’s *Roe v. Wade* decision to permit abortions.

**1974**
Church attendance down to 40% weekly in the US from about 65% a decade earlier.

**1978**
Death of Austrian mathematician Kurt Gödel, who proves that pure mathematical reductionism does not work; he also opposes the view espoused by Alan Turing that all thinking is “computational.”

**1980**
Death of Swiss developmental psychologist Jean Piaget.

**1980s**
Rise of Japan and the other Pacific Rim countries as economic powers and important contributors to science.

**1981**
Identification of the AIDS virus (the epidemic may have begun circa 1977).

**mid-1980s**
Significant progress in neuroscience in the areas of memory (Kandel, Miskin, Squires-Wheeler), computer modeling of neuronal activities (Edelman, Rumelhart, McClelland), mathematical/philosophical approaches to the question of “computability” of the mind (Penrose, Searle, Minsky, the Churchlands), neuroimaging (Andreasen, the Gurs, the Shaywitzes), the circuitry underlying obsessive–compulsive disorder (Insel, Baxter, Kellner, Rubin), the nature of consciousness (Dennett).

**1986**
The Chernobyl nuclear-plant disaster erupts near Kiev.

**1987**
Gorbachev introduces glasnost (openness) and perestroika (restructuring) into the Russian political scene; becomes president of the USSR the following year.

**1989**
Collapse of the Communist regime in the USSR; beginning of fractionation into independent states, with democratically elected chiefs.

Are there Biological Commonalities among Different Psychiatric Disorders?

Christopher Pittenger

Introduction

Psychiatric diagnosis is in a state of flux (Kupfer et al. 2002, Zachar and Kendler 2007). Recent editions of the standard manual of American psychiatric diagnosis, the Diagnostic and Statistical Manual (DSM), have espoused a neo-Kraepelinian diagnostic framework, wherein disorders are divided into discrete, often mutually exclusive entities on the basis of their symptoms (American Psychiatric Association 1980, 1994). This theory-neutral framework has enhanced the precision of psychiatric diagnosis and thereby accelerated psychiatric research over the past 25 years. Recent data challenge this framework, however, by emphasizing common features among ostensibly discrete disorders.

The National Comorbidity Survey, which examined the epidemiology of psychiatric disease across the population, illustrates the challenges faced by the categorical diagnostic system laid out in DSM-III and DSM-IV-TR. A startling percentage of patients with one disorder were found to have one, two, or more additional diagnoses. Moreover, the number of diagnoses correlated highly with the severity of symptoms (Kessler et al. 1994). This may suggest that the sickest psychiatric patients have an underlying vulnerability or predisposition toward psychopathology, independent of the particular symptoms expressed and of the specific diagnosis they receive under our current system.

This picture of commonality among disorders more closely resembles the schema of Griesinger than that of Kraepin. Griesinger proposed in the 19th century that there is a single protean psychiatric disorder (Enheitspsychose) whose expression in different patients is modulated by continuously variable traits. With the next edition of the DSM planned for 2010, an active debate is underway as to what form psychiatric nosology should take (Kupfer et al. 2002). One important perspective in this debate is that of the neurobiology of psychiatric disorders, which has been advancing at an accelerating rate. This conceptual debate—whether psychiatric disease is best conceptualized in terms of discrete entities or of overlapping continua—therefore motivates the central question of this chapter; namely, are there biological commonalities among different psychiatric disorders?

In this chapter, and by way of introduction to the more focused discussions that follow, we explore evidence for the thesis that disorders that we currently consider to be distinct entities often have overlapping or shared biological underpinnings. In the first section, we briefly explore the general relationship between brain and behavior, and thus between disorders of brain function and psychiatric disease. We then provide examples of epidemiological, clinical, neuropathological, and genetic evidence for biological commonalities among different disorders. Finally, we explore a cognitive neuroscience perspective on this question in more detail. In so doing, we discuss how an understanding of the normal functions of different brain circuits informs hypotheses about the consequences of their disruption in psychiatric disease, and therefore how dysregulation of the same brain circuits across different disorders can shed light on aspects of their overlapping symptomatology. Throughout, we focus largely on three major disorders—schizophrenia, major depressive disorder, and drug addiction—making reference to other conditions where appropriate. While this discussion only scratches the surface of the rich neurobiology of these structures and the larger networks in which they are embedded, it serves to illustrate the contributions of an advancing neurobiological knowledge-base to our understanding of psychiatric neurobiology, of diagnosis and, it is to be hoped, of treatment.
Diseases of the Mind and Diseases of the Brain

Mind and Brain in Psychiatric Disease

Hippocrates first proposed a fundamental relationship between disordered behavior and disordered brain function. In the treatise on epilepsy entitled “On the Sacred Disease,” Hippocrates decries those who would ascribe this behavioral malady to an extracorporeal cause: “They who first referred this malady to the gods appear to me to have been just such persons as the conjurors, purifiers, mountebanks, and charlatans.” Rather, he wrote that “the brain is the cause of this affliction, as it is of other very great disease” (Hippocrates 1952).

This correspondence has not always seemed obvious. Descartes’ substance dualism formalized the intuitive divide between functions of the body and functions of the mind, a division that continues to color Western thinking about brain and behavior. A dualist perspective persisted in formal psychiatric diagnosis into the latter part of the 20th century in the form of the organic/nonorganic distinction that was present in DSM-III (American Psychiatric Association 1980, Spitzer et al. 1989). Indeed, research into psychiatrists’ diagnostic practices and assignment of personal responsibility for symptoms of psychiatric disease reveals persistent dualist tendencies to this day (Miresco and Kirmayer 2006). However, the organic/nonorganic distinction was abandoned with DSM-IV in 1994 (American Psychiatric Association 1994), and by the end of the 20th century the equation of behavioral disorders with pathological brain states had become a fundamental tenet of psychiatry (Kandel 1998, Kendler 2005).

The simple statement that psychiatric disorders are brain disorders masks enormous complexity. Clear, unitary causes of symptoms are rare in psychiatry. One example is found in the once common affliction known as general paresis of the insane. This condition, which was enormously common in the 19th and early 20th century, was a dreaded combination of psychosis, progressive dementia, and paralysis. In 1913 Noguchi and Moore discovered that general paresis results from tertiary syphilis, or chronic infection of the brain by the spirochete Treponema pallidum. When penicillin was found to kill the spirochete, general paresis became not only treatable but completely preventable if syphilis was treated early. This became a powerful paradigm of simple causation: a psychiatric entity, characterized by dramatic abnormalities in behavior and cognition, which was found to have a specifiable, straightforward biological cause, permitting a definitive new treatment.

Such single necessary and sufficient etiologic agents are, however, the exception in psychiatry. More often, multiple causal factors, each with a small effect, act in concert to produce disease. Moreover, the effects of causal factors may be described at multiple levels of scientific investigation. For example, in the case of major depressive disorder—an example to which we will return throughout this chapter—alterations have been reported in many different neurobiological processes. Genetic loci with a role in the vulnerability to major depression include regulators of monoaminergic neurotransmission as well as neurotrophic factors (Levinson 2006). Antidepressant drugs primarily act on the serotonergic and noradrenergic systems, but some antidepressant drugs also interact with receptors for the neuropeptides corticotropin-releasing factor and substance P, glucocorticoids, the NMDA glutamate receptor, and cholinergic receptors (Holtzheimer and Nemeroff 2006). Functional and structural imaging has implicated dysfunction in dorsolateral prefrontal cortex, orbitofrontal cortex, cingulate cortex, and hippocampus. Postmortem studies indicate alterations in the number of glia in multiple brain regions as well as changes in neuronal density and the size of neuronal cell bodies (Rajkowska 2003) and a reduction in subpopulations of interneurons (Rajkowska et al. 2007). The etiology and biology of a disorder in which so many diverse genetic mechanisms, neurochemical systems, brain regions, and cellular abnormalities have been implicated are likely to be complex and multifactorial. The daunting complexity of psychiatric disorders therefore raises this question: how may one meaningfully investigate biological commonalities between disorders?

Endophenotypes in Psychiatry

One fruitful way to come to terms with this complexity is through the analysis of endophenotypes. An endophenotype is a measurable neurobiological or psychological parameter that meaningfully contributes to an aspect of a psychiatric disorder but is simpler, less heterogeneous, and more closely tied to measurable aspects of the underlying biology. The study of working memory as an endophenotype, for example, has contributed greatly to an understanding of cognitive dysfunction in schizophrenia—an example that will be explored in greater detail later in this chapter. Endophenotypes may also be shared across overtly distinct disorders, as illustrated by the presence of working memory impairments in schizophrenia, major depression and attention-deficit hyperactivity disorder (ADHD). Investigations focusing on endophenotypes may therefore help bridge the explanatory gap between ultimate etiologic causes, such as genetic or environmental variables, and resulting psychiatric phenomenology (Gottesman and Gould 2003) and thereby provide a handle on biological commonalities.

In the latter portion of this chapter, we explore psychiatric endophenotypes from a cognitive neuroscience perspective. The premise for our arguments is that certain discrete psychological functions are mediated through consistent, definable neural circuitry. Deficits in these psychological functions (i.e., endophenotypes) are therefore likely to be associated with abnormalities in the associated neural circuits. Furthermore, the presence of similar endophenotypes in otherwise disparate disorders predicts that related alterations may be observable in the same neural circuitry. This approach to understanding different psychiatric disorders provides a powerful framework in which to conceptualize mental illness; namely, as a set of conditions that come about due to different combinations of endophenotypes. Therefore, a larger category of illness, such as schizophrenia or depression, may be better “carved at its joints” along endophenotypic lines.

Specific Biological Commonalities Among Disorders

As mentioned earlier, evidence for shared biological perturbations across different psychiatric disorders can be sought in many domains. Before exploring a cognitive neuroscience perspective, we first briefly describe other ways in which
different psychiatric disorders can be seen to have overlapping biological underpinnings.

**Genetic Commonalities**

Specific alleles of certain genes have been associated with multiple psychiatric disorders. For example, a polymorphism in the promoter region of the serotonin reuptake transporter (SERT) gene, which influences the efficiency of removal of serotonin from synapses, has been associated with numerous psychiatric disorders, including depression, psychosomatic disorders, alcoholism, smoking, eating disorders, ADHD, and autism (reviewed in Serretti et al. 2006). Similarly, polymorphisms in the dopamine beta hydroxylase (DBH) gene, whose product is the last step in the synthesis of norepinephrine from dopamine, have been associated with schizophrenia, cocaine-induced paranoia, depression, ADHD, and alcoholism (reviewed in Cubells and Zabetian 2004). The association of the same genetic polymorphism with several different disorders directly suggests shared neurobiological underpinnings.

Possession of a disease-associated gene variant, however, rarely guarantees development of disease. Rather, the risk of developing disease often derives from interaction of genetic contributors with environmental factors (e.g., Caspi et al. 2003). This fact further complicates an understanding of shared mechanisms across psychiatric disorders, leading to complex causal webs (e.g., Kendler et al. 2002, 2006).

**Environmental Etiologies**

Important nongenetic etiological factors can also contribute to different psychiatric conditions. For example, childhood stress, including abuse and parental loss, is an important etiological contributor to major depression (e.g., Kendler et al. 2002, 2006), posttraumatic stress disorder (PTSD) (e.g., Pine and Cohen 2002), and borderline personality disorder (e.g., Lieb et al. 2004). This overlap suggests that the neurobiological consequences of childhood stress may be relevant to all of these disorders. Numerous other examples of etiological factors shared among discrete psychiatric disorders can be found in this textbook, and others will doubtless come to light as our understanding of the etiology of neuropsychiatric disease grows.

**Neurochemical Commonalities**

Disruptions in defined neurochemical systems can contribute to a variety of psychiatric disorders. For example, dysregulation of dopaminergic neurotransmission is found in schizophrenia, affective disorders, and substance abuse (e.g., Mann 2003, Franklin et al. 2005). Disruption of noradrenergic neurotransmission is implicated in anxiety disorders, affective disorders, suicide, substance abuse, and PTSD (e.g., Mann 2003). Serotonin dysregulation has been linked to affective disorders, anxiety, PTSD, and many other conditions (e.g., Mann 2003). Dysregulation of glutamatergic neurotransmission has been linked to depression (e.g., Kugaya and Sanacora 2005, Pittenger et al. 2007), obsessive—compulsive disorder (OCD) (Pittenger et al. 2006a), anxiety disorders (e.g., Simon and Gorman 2006), and drug addiction (Kalivas et al. 2005). The fact that dysregulation of these neurochemical systems can contribute to so many different psychiatric disorders points yet again to shared neurobiological substrates.

**Histopathological Similarities**

The characterization of histopathological abnormalities in psychiatric disorders is still in its infancy. Gross anatomical abnormalities suggestive of underlying cellular change, such as enlarged ventricles and widened sulci in dementia and schizophrenia, have been well characterized for some time (e.g., Steen et al. 2006), but documentation of more specific pathological changes in the brains of individuals with major psychiatric disorders has been harder to come by. Nonetheless, it is becoming clear that here, too, overlapping histopathological changes can correspond to different neuropsychiatric disorders. For example, reduced numbers of glial cells in regions of cortex have been described in major depression (Rajkowska et al. 1999), bipolar disorder (Rajkowska et al. 2002), alcohol dependence (Miguel-Hidalgo et al. 2002), and schizophrenia (Rajkowska et al. 2002). Functional or structural disruption of GABAergic interneurons has been described in schizophrenia (Lewis et al. 2005), major depression (Rajkowska et al. 2007), and Tourette syndrome (Kalanithi et al. 2005).

**Gross Anatomical Changes**

The involvement of the same neuroanatomical structures can point the way to overlapping biology between disorders. Structural imaging studies have revealed several such examples. For example, reduced hippocampal size has been observed in depression, PTSD, Alzheimer’s dementia, and schizophrenia (e.g., Sapolsky 2000, Gilbertson et al. 2002, Steen et al. 2006).

**Beyond Gross Anatomical Similarities: Functional Circuitry in Psychiatric Disease**

Mental functioning derives from the operation of large groups of neurons, organized into nuclei, brain regions, and neural circuits. Understanding brain function in terms of functional neural circuitry is the domain of cognitive neuroscience, an approach enabled in part by advances in functional neuroimaging over the past few decades. A cognitive neuroscience perspective allows for integration across other levels of analysis, reflecting the functional consequences of genetic, neurochemical, histopathological and gross anatomical alterations in more psychologically meaningful terms.

The hippocampus provides a useful introductory example (Figure 15–1). As noted above, reduced hippocampal size and other pathological changes have been noted in several neuropsychiatric diseases, including major depression, PTSD, and some forms of dementia. Functional characterization of the hippocampus, in human neuroimaging studies, lesion studies, and animal models, reveals that it contributes critically to the formation of memories for both facts and events (e.g., Scoville and Milner 1957, Tulving 2002, Squire et al. 2004). It would be predicted, then, that memory may be impaired in those disorders in which disruption of hippocampal function has been described. And, indeed, declarative memory is impaired—most obviously in dementias such as Alzheimer’s disease, but also in major depression and PTSD (Sapolsky 2000). The hippocampus also has an important role in the regulation of the stress response, as orchestrated in part by the hypothalamus-pituitary—adrenal (HPA) axis. And indeed, HPA axis regulation and the stress response are dysregulated in major depression, PTSD, and some
dementias (McEwen 2004). Hippocampal dysfunction represents an endophenotype of multiple disorders.

This neural circuitry perspective on the question posed in this chapter—whether disparate psychiatric disorders have shared neurobiological underpinnings—has particular advantages, beyond its cogency in individual cases, that motivate its further exploration. First, by its nature it is of heuristic value in understanding the relationships between specific brain functions and the phenomenology of psychiatric disease. Second, it motivates the study of brain biology by psychiatric clinicians. Third, it represents a fruitful guide to future research: when seeking neurobiological data on a poorly understood psychiatric disorder, it is useful to examine brain areas whose normal function is known to correspond to domains in which the disorder’s symptomatology is expressed.

Finally, examination of circuits that are perturbed in different psychiatric disorders is likely to inform the rational categorization of psychiatric disease, and is therefore likely to contribute to the ongoing debate as to what form DSM-V nosology should take. This is true for either a categorical or dimensional conception of psychiatric disease. If two conditions are shown to correspond to qualitatively different functional perturbations of a defined brain circuit, with minimal overlap, then different categorical diagnoses may be appropriate—even if the conditions are phenomenologically similar. Such a discovery might help differentiate a complex syndrome, such as major depression, into meaningfully different subtypes. Conversely, if two conditions are found to be characterized by qualitatively similar perturbations of a particular underlying brain circuit, they might best be conceptualized as lying along a continuum—even if they present quite differently at the clinical level. This might be the case, for example, in psychotic depression, psychotic mania, and schizophrenia, which could contribute to a dimensional categorization of psychosis that transcends our current diagnostic system.

We spend the remainder of this chapter exploring this perspective on the shared biology of distinct psychiatric diseases. We focus on four particular circuits: the ventral striatum, the dorsal striatum, the anterior cingulate cortex, and the dorsolateral prefrontal cortex. While this treatment cannot be exhaustive, it demonstrates the utility of a cognitive neuroscience perspective and exhibits how commonalities between disorders at the level of brain circuitry can reveal relationships that may inform psychiatric diagnosis in the future.

The Ventral Striatum and Mechanisms of Reward

As Freud famously emphasized, many of our actions are driven, directly or indirectly, by the quest for reward—food, sex, power, affiliation, acclaim. Investigation of the neurobiology of reward has revealed a central role for the ventral striatum, especially the nucleus accumbens, and related structures such as the orbitofrontal cortex and ventral tegmental area (VTA) in reward-driven behavior and reinforcement learning.

The striatum can be divided into at least two functionally distinct regions, the dorsal striatum (the caudate and putamen) and the ventral striatum (Figure 15–2; Haber 2005). The ventral striatum receives input from the orbital and medial frontal cortex, the hippocampus, the amygdala, and the thalamus. It also receives a prominent dopaminergic projection from the VTA, which has profound effects on motivational processing.

The cells of the VTA fire spikes, leading to phasic dopamine release in the nucleus accumbens, when an animal encounters an unexpected reinforcer—precisely the circumstances under which reinforced learning occurs (Schultz 2006). All addictive drugs also result in dopamine release in the nucleus accumbens (Wise and Rompre 1989, Hyman et al. 2006). Perturbations of the nucleus accumbens in experimental animals alter motivated behavior in response to reward.
to drugs of abuse (e.g., Carlezon et al. 1998) and to naturally occurring reinforcers, including sex (e.g., Barrot et al. 2005), food (Georges et al. 2005), and emotional stimuli (Barrot et al. 2002). Similarly, the human ventral striatum, together with its orbitofrontal afferents, is central to the processing of reward expectation and response (McClure et al. 2004, Phan et al. 2002, Kringelbach 2005).

**Dysregulation of Reward in Disorders of the Ventral Striatum**

**Drug Addiction**

Dopamine release in the nucleus accumbens correlates with the “high” associated with consumption of drugs of abuse. Increased dopamine release in the orbitofrontal cortex, which projects to the accumbens, correlates with drug craving—the motivation to engage in behaviors aimed at procuring more of the abused substance (Volkow et al. 1997). In experimental animals, triggering of drug seeking by stress, drug-associated cues, or drug administration depends on activation of the accumbens by a glutamatergic projection from the prefrontal cortex (e.g., McFarland et al. 2003). Modulation of this circuitry is therefore likely to be important in future therapeutic strategies aimed at reducing relapse into drug use (reviewed by Kalivas and Volkow 2005).

Human and animal studies have demonstrated pathological changes in this prefrontal-accumbens circuitry after extended drug use. In cocaine users, dopamine release is attenuated in the ventral striatum, suggesting a compensatory response to chronic overstimulation (Volkow et al. 1997). Basal prefrontal metabolic activity is also reduced in drug addicts (reviewed in Kalivas and Volkow 2005). In animals, there are a variety of changes in the glutamatergic projection from the prefrontal cortex to the ventral striatum after chronic cocaine exposure (reviewed in Kalivas et al. 2005). Experimental manipulations in the nucleus accumbens can, in turn, alter animals’ behavioral responses to cocaine and other drugs of abuse (e.g., Carlezon et al. 1998). The chronic functional alterations in the reward-regulating circuitry correspond to the profound dysregulation of reward that is one of the core features of the addicted state.

**Mood Disorders**

Depression and mania are characterized by opposite abnormalities of motivation and reward. Anhedonia, the blunting of motivation and pleasure, is one of the cardinal symptoms of major depression. Several functional neuroimaging studies have suggested that hypometabolism of the ventral striatum may underlie these symptoms (Dunn et al. 2002). For example, in depressed subjects Epstein et al. (2006) found reduced ventral striatal activation to positively valenced words; this reduction correlated with the intensity of their anhedonia. Studies in animal models of depression likewise implicate ventral striatal function in aspects of a depression-like state (Nestler and Carlezon 2006). Convergent evidence, therefore, implicates dysfunction of the ventral striatum in the anhedonia of depression. This circuit-level understanding of the etiology of anhedonia has recently received a dramatic application and test, when Schlaepfer et al. used direct stimulation of the nucleus accumbens as a treatment for profoundly refractory major depression, with promising initial results (Schlaepfer et al. 2007).

Manic patients display the inverse of anhedonia (Hasler et al. 2006), such that reward-driven behaviors are heightened. Typically, manic patients are driven to pursue the most immediate and potent rewards, namely food, sex, social attention, money, and drugs of abuse. The role of the ventral striatal reward circuitry in bipolar disorder is poorly understood. However, structural and functional imaging studies of bipolar disorder indicate dysfunction in a circuit that includes the ventral striatum (reviewed in Blumberg et al. 2004, Strakowski et al. 2005). For example, reduced gray matter in both ventral striatum and the anterior cingulate cortex have been shown to be associated with genetic risk for bipolar disorder (McDonald et al. 2004). It is plausible that the hyperhedonic state of mania correlates with dysregulated overactivity of the ventral striatum and associated structures involved in reward and reinforcement—the opposite of the effect seen in major depression.

**Schizophrenia**

Anhedonia is also a cardinal symptom of schizophrenia. Indeed, this negative symptomatology is often more chronic and more disabling than the more colorful, episodic positive symptoms of psychosis. Perturbation of ventral striatal function may contribute to this aspect of schizophrenia. All effective antipsychotics are antagonists at the D2 subclass of dopamine receptors (reviewed in Kapur et al. 2006), which are prominent throughout the striatum. The ventral striatum of schizophrenics shows a blunted response to rewarding stimuli, which correlates with negative symptoms (Juckel et al. 2006) and appears analogous to anhedonia in major depression (e.g., Epstein et al. 2006). The blunting of ventral striatal reactivity in both schizophrenia and major depression suggests important overlap between the underlying neurobiology of these syndromes.

**The Dorsal Striatum and the Automation of the Routine**

Many everyday actions have an automatic character. When driving a new road, attention is fully engaged. We respond flexibly to events and cues; we note associations between them and form explicit memories of the process. This contrasts with the experience of driving an overlearned route, like a daily commute. When driving such a route, it is a common experience to suddenly find oneself at one’s destination, having performed a complex series of behaviors without engaging much attention or forming any explicit memories at all. This automation of the routine is adaptive in that it frees attentional resources for other tasks, but it comes at a cost in behavioral flexibility. When engaged in a habitual pattern of responses, effort is required to deviate from the familiar pattern, as when one drives “on autopilot” to a familiar destination even when today’s goal differs from the norm.

Several lines of evidence implicate a circuit including the dorsal portion of the striatum—the caudate nucleus and putamen—in the automation of routine, overlearned behaviors (Mishkin and Petri 1984, Packard and Knowlton 2002, Yin and Knowlton 2006). The caudate and putamen, which regulate multiple aspects of behavior including motor patterning, oculomotor control, and habit learning, receive projections from virtually the entire neocortex and several subnuclei of the thalamus, along with modulatory input from hippocampus and other structures. They, in
Maladaptive Habits in Disorders of the Dorsal Striatum

Obsessive–Compulsive Disorder (OCD)
OCD is characterized by intrusive, anxiety-provoking, irrational thoughts, and compulsive behaviors that attempt to relieve the anxiety that attends them. The stereotyped and automatic character of these thoughts has the appearance of a habitual cognition gone awry, suggesting that dysregulation of the dorsal striatum might contribute to the underlying neurobiology of OCD. Indeed, a circuit consisting of the orbitofrontal cortex, the striatum, and the thalamus has consistently been shown to be hyperactive in patients with OCD, and this pathological activation is moderated in parallel with symptom improvement after treatment with either psychotherapy or pharmacotherapy (reviewed in Jenike 2004). Learning of a striatum-dependent implicit sequence-learning task (Deckersbach et al. 2002) and of an implicit card-learning task (Joel et al. 2005) are disrupted in OCD, suggesting that the function of the striatum in learning new automated behaviors are disrupted by this circuit-level dysregulation. Further work will be needed to investigate whether this disruption contributes to the rigid habit-like structure of some OCD symptomatology.

Drug Addiction
Drug seeking is often initially motivated by the desire for pleasure or reward, and then at times by attempts to minimize the dysphoria of craving and withdrawal; as noted above, the ventral striatum and related circuitry play a major role in these phenomena. Later, with the development of true addiction, compulsive, habit-like behaviors develop—drug-associated behaviors that are executed automatically. These drug-associated behaviors, which are likely to derive from a subversion of the mechanisms of normal stimulus-response habit learning, are a particularly pernicious aspect of addiction, as they occur without conscious control and are resistant to extinction (Tiffany 1990, Robbins and Everitt 1999, Everitt and Robbins 2005). Automated drug-associated behaviors are likely to represent an important target in the development of novel treatments for addiction.

These observations predict dysregulation of the dorsal striatum in addicted states. Indeed, observations in animal models link compulsive drug-seeking behaviors to the dorsal striatum (Vanderschuren and Everitt 2004, Vanderschuren et al. 2005). In humans, cocaine dependence is associated with increased volume of the dorsal striatum (Jacobsen et al. 2001). Moreover, the dorsal striatum may have a particularly important role in drug seeking after abstinence in animals (Fuchs et al. 2006) and humans (Sinha et al. 2005).

The association of perturbed dorsal striatal function with maladaptive, habit-like behaviors in OCD and drug addiction suggests an important role for the habit-forming circuitry of the dorsal striatum in these and related forms of psychopathology. This points to a commonality between disorders that are widely separated in our current diagnostic system, and may point the way to the development of new therapies specifically aimed at the mechanisms of habit formation.

Prefrontal Cortex: Attention and Behavioral Flexibility
The capacity for creative, context-responsive flexibility in behavioral responses—termed “top-down” cognitive control or executive functioning—is a function of the frontal lobes. The prefrontal cortex (PFC) is typically not required for the learning or performance of simple tasks. But when task demands change, the PFC is required for proper adjustments in behavior to maintain accuracy. This role for the PFC in cognitive control is seen in humans (Milner 1963), nonhuman primates (Dias et al. 1996), and even in rodents (Birrell and Brown 2000). More broadly, the PFC is responsible for maintaining an internal representation of current goals and modulating activity in brain regions responsible for perception or action in order to flexibly achieve these goals. In order to accomplish this, the PFC must be able to (1) maintain a representation of goals in the face of distraction (working memory), (2) update these representations as new information is received, through multiple sensory modalities, and (3) provide a feedback signal that can select the neural pathways appropriate for the current task context (Miller and Cohen 2001).

In humans, frontal cortical cognitive control mechanisms have been probed using a variety of behavioral tasks. Cognitive control tasks of various sorts recruit a consistent prefrontal network, which includes the dorsolateral PFC (DLPFC) (Duncan and Owen 2000) (see Figure 15–3). In the classic color-word Stroop task (Stroop 1935), for example, subjects have to name the ink color of a word whose meaning is either congruent (e.g., GREEN printed in green ink) or incongruent with the ink color (e.g., GREEN printed in red ink). Naming the ink color in an incongruent trial requires subjects to ignore word meaning. The conflict between the ink color and the incongruent word meaning shows reaction times and increases errors, a phenomenon known as the Stroop effect.

When subjects experience conflict on an incongruent Stroop trial, however, they also reflexively prepare for a subsequent incongruent trial. Consequently, reaction time becomes faster on the second of two consecutive incongruent trials. This anticipatory adjustment in cognitive control for the purpose of performance improvement has been linked to activation of the DLPFC (Kerns et al. 2004).
Consistent with this, subjects with frontal lobe lesions have difficulty dealing with color-word conflict and make more errors in the Stroop task (Vendrell et al. 1995). The DLPFC achieves this top-down cognitive control in part by enhancing the sensory representation of an object at the focus of attention (Egner and Hirsch 2005).

The capacity for increasing cognitive control to meet task demands, however, is not unlimited. This is illustrated by the n-back task, in which subjects must decide on each trial whether the current stimulus matches the one shown 1, 2, or 3 trials back. Doing so requires the sequential updating of working memory content, and maintenance of task goals in the face of increased working memory load. Frontal lobe lesions lead to more errors at greater working memory loads in this task (Muller et al. 2002). Activity in the DLPFC increases as task demands increase through the 0-, 1- and 2-back conditions (Callicott et al. 1999). As subjects’ working memory capacities are exceeded at the more difficult 3-back condition, however, both subjects’ performance and dorsolateral prefrontal activity decline relative to the 2-back condition.

**Chapter 15 • Are there Biological Commonalities among Different Psychiatric Disorders?**

**Attentional Deficits in Disorders of the Prefrontal Cortex**

**Schizophrenia**

Psychosis often dominates the initial presentation of schizophrenia. However, negative symptoms and cognitive dysfunction, including impairments in executive function and working memory, are more chronic, better predict poor outcome, and are not substantially helped by available pharmacotherapies (Harvey et al. 2004). Patients with schizophrenia typically perform worse than control subjects in many neuropsychological tests of frontal lobe function, and this deficit has been linked to greater disorganization of thought and speech (Kerns and Berenbaum 2002). It is of great interest, therefore, to examine prefrontal cortical function in schizophrenics during tasks that require elements of the cognitive control processes discussed above.

Neuroimaging studies of working memory have indeed found abnormal activation of DLPFC in these patients, but of inconsistent direction: while some studies have found hypoactivation in schizophrenics, others have found hyperactivation. This seeming inconsistency in the data led to debate about the nature of the neuropsychologically suggested “hypofrontality” of patients with schizophrenia.

A solution to this debate arose from the finding that activity in the DLPFC of healthy subjects decreases from its peak as working memory is stressed beyond its maximal capacity (Callicott et al. 1999). If the DLPFC of schizophrenic patients operates less efficiently than that of controls, patients may be found to hyperactivate this region as they strain to keep up with low working memory loads that control subjects can easily handle, and hypoactivate this region at higher working memory loads that exceed patients’ working memory capacity, but not that of controls (Callicott et al. 2003b). In other words, whether relative hyper- or hypofrontality is found in imaging studies depends on the presence of performance differences between patients and controls. Unaffected siblings of schizophrenics, who carry some of the genetic load for the disease, were found to hyperactivate the DLPFC relative to performance-matched controls in a working memory task, consistent with reduced processing efficiency in this region (Callicott et al. 2003a).

**Depression**

Patients with major depression also often display neurocognitive deficits consistent with frontal lobe dysfunction, though the deficits are generally not as severe as those seen in schizophrenia (reviewed in Rogers et al. 2004). Imaging studies of resting blood flow or metabolism have supported the view that cognitive control circuitry is perturbed in depression. A number of studies have noted DLPFC hypometabolism in depressed patients (Drevets 1999). These findings support an influential theory of depression, which suggests that hypofunction of the DLPFC and related prefrontal regions accounts for the cognitive symptoms of depression—problems with attention, concentration, and memory (Mayberg 2003). The relationship between these abnormalities and the central mood and motivational symptoms of depression, however, remains unclear.

Neuroimaging studies of activation during cognitive control tasks such as those discussed above have further suggested inefficiency of DLPFC activity in depressed patients. This is true both for the Stroop task (Wagner et al. 2006) and the n-back task (Harvey et al. 2005). These studies, however, suggest that while the DLPFC is inefficient in major depression, its capacity for increasing its activity to match task demands is not as easily overwhelmed as that of the DLPFC of schizophrenics.

**Prefrontal Cortex: “Deliberate” Versus “Implicit” Emotion Regulation Strategies**

We are constantly exposed to a larger number of sensory stimuli than our sensory and cognitive resources can process. Representations of individual stimuli therefore compete
for attentional selection to determine which will be further processed, retained in memory, or used for preparation for action; this is known as the biased competition model of attention. Emotionally salient stimuli are widely believed to have a special advantage in this competition, as evaluation of an emotional stimulus may be critical for predicting threat or reward. Because emotional stimuli nonetheless must compete for further processing, regulation of the effects of emotional stimuli is thought to occur through the same cognitive control process that selects between competing nonemotional stimulus representations.

Gross (2002) has proposed a framework for classifying different emotion regulation strategies. One important distinction is between “antecedent-focused” strategies, which aim to alter emotional responses before they begin, and “response-focused” strategies, which suppress emotional responses after they have been initiated. Antecedent-focused strategies include willful detachment, distraction, and cognitive reappraisal; response-focused strategies include voluntary suppression of positive or negative emotional reactions. Unstated within this framework is that an emotion regulation strategy may be “deliberate,” requiring conscious top-down intentionality, or “implicit,” engaging top-down regulation of emotional processes without requiring conscious intentionality.

Several recent neuroimaging studies of the neural circuitry associated with deliberate efforts at emotion regulation (Beauregard et al. 2001, Kalisch et al. 2005, Kalisch et al. 2006, Levesque et al. 2003, Ochsner et al. 2004) find that deliberate emotion regulation involves the DLPFC, which is associated with top-down cognitive control, regardless of whether an antecedent-focused or a response-focused strategy is being employed. This view of emotion regulation, moreover, suggests that in any disorder in which the DLPFC is dysfunctional, such as in schizophrenia and depression, one might expect deficits in deliberative forms of emotional regulation. Difficulty regulating emotion in this manner would be a specific instance of a more general cognitive control deficit.

A different picture emerges when one considers implicit forms of emotion regulation. Implicit emotion regulation is based on an individual’s expectation or anticipation of emotional stimuli, but without the explicit goal of emotion regulation, and appears to be mediated by top-down regulation of limbic structures by the rostral (pregenual) portion of the anterior cingulate cortex (rACC) and adjacent ventromedial PFC (vmPFC) (see Figure 15–3). These regions have direct projections to regions involved in emotion, such as the amygdala and brain stem. Studies in the likely rodent homologs of these areas also suggest that these projections are inhibitory in nature (Quirk et al. 2003). Importantly, abnormalities in circuitry mediating implicit emotional regulation can be seen in emotional dysregulation disorders in which no dorsolateral prefrontal deficits are observed (Etkin and Wager 2007).

To frame implicit emotional regulation more clearly in the experimental methods employed by the cognitive control literature, Etkin et al. (2006) recently developed an emotional analog to the color-word Stroop task. They showed subjects images of fearful or happy facial expressions and asked them to identify the affect. Written across the faces were the words “fear” or “happy,” which were either of the same affect (congruent) or of a different affect (incongruent) as the facial expression. As in the color-word Stroop task, subjects were to ignore the text but were unable to avoid involuntarily reading the word and extracting its meaning. The emotional meaning of the words thus led to direct conflict with interpretation of the facial affect. As a result, incongruent stimuli interfered with affect identification in all subjects.

Resolution of emotional conflict in this task activated the rACC, rather than the DLPFC. Rostral anterior cingulate activation was accompanied by a simultaneous and correlated reduction in amygdala activity. These results are consistent with a recent study of the extinction of conditioned fear responses, in which subjects evaluate and override expectations for aversive stimuli. Fear extinction involved increased activity in the rACC and vmPFC and decreased activity in the amygdala (Phelps et al. 2004). Likewise, rostral anterior cingulate activation has also been observed during placebo anxiety reduction, a process in which control over an emotional stimulus (an aversive picture) is recruited to diminish the effect of the emotional stimulus (Petrovic et al. 2005).

**Dysfunctional Emotion Regulation in Disorders of the Prefrontal Cortex**

**Posttraumatic Stress Disorder (PTSD)**

PTSD is characterized by prominent emotional dysregulation. Patients experience disproportionate arousal—often to stimuli processed outside of conscious awareness—and have exaggerated startle responses, vivid intrusive thoughts, and unbidden images in the form of flashbacks and nightmares related to past trauma (Ehlers and Clark 2000). Patients may go to great lengths to avoid physical or psychological trauma reminders, and may experience dissociative symptoms or emotional numbing. It has been suggested that PTSD is a disorder of excessive conditioned fear, triggered by a severe and often discrete traumatic event (Ehlers and Clark 2000). This view, however, appears to explain only some PTSD symptoms; in particular, it leaves out the symptoms of emotional dysregulation, such as dissociation, emotional numbing, and intrusive thoughts and images.

Neuroimaging studies have searched for markers of abnormal fear responses and abnormal emotion regulation. Amygdala hyperactivity in patients has been noted in a number of these studies (reviewed in Bremner 2004) and has been used to support an excessive fear conditioning model of PTSD. Significant inconsistencies exist in the neuroimaging literature, however, as a number of similar studies have reported no abnormality, or even hypoactivation, in the amygdala of patients with PTSD (Etkin and Wager 2007).

More consistently observed is hypoactivation within the rACC and vmPFC in patients with PTSD (Bremner et al. 2004). DLPFC deficits, in contrast, have not been reported. Moreover, data from other anxiety disorders in which excessive conditioned fear has been proposed to be an important mechanism—social anxiety disorder and specific phobia—suggest that rACC and ventromedial prefrontal hypoactivation is specific for PTSD (Rauch et al. 2003, Bremner et al. 2004, Shin et al. 2006, Etkin and Wager 2007). Thus, these data suggest that emotional dysregulation in PTSD is related to abnormalities in implicit forms of emotion regulation, which...
involve the rACC and vmPFC, and spares more deliberate forms of emotion regulation that rely on DLPFC cognitive control mechanisms.

Depression
Helen Mayberg has developed a model of depression (Mayberg 2003) in which the rACC serves as a regulator region, linking dorsal cognitive/attentional circuitry (dorsal anterior cingulate and DLPFC) with ventral emotional/vegetative circuitry (subgenual anterior cingulate, amygdala, brain stem, and hypothalamus). A number of studies have noted a positive correlation between the outcome of antidepressant treatment and pretreatment levels of rACC activity. A landmark PET study of the pharmacological treatment of unipolar depression, for example, found that resting activity in the rACC uniquely differentiated treatment responders from nonresponders (Mayberg et al. 1997); responders were hypermetabolic prior to treatment with respect to controls, while nonresponders were hypometabolic. Subsequent studies have found similar positive correlations between pretreatment rACC activity and outcome in response to paroxetine (Saxena et al. 2003), nortriptyline (Pizzagalli et al. 2001), venlafaxine (Davidson et al. 2003), and partial sleep deprivation (Wu et al. 1999). Importantly, these results generalize across widely varying neuroimaging methods, including resting FDG-PET (Mayberg et al. 1997, Saxena et al. 2003, Wu et al. 1999), fMRI activation to emotional stimuli (Davidson et al. 2003) and resting EEG (Pizzagalli et al. 2001). Consistent with the outcome-based studies above, an fMRI study of treatment-resistant depression found hypoactivity in the rostral rACC of patients in response to both positive and negative affective pictures (Kumari et al. 2003).

Together, these data suggest that certain treatment-resistant subtypes of depression involve hypofunction of the rACC. If the rostral anterior cingulate is critical for implicit emotional regulation, as suggested above, then its hypofunction may indicate poor capacity to modulate negative emotion. It is furthermore interesting to note that while consistent findings have been observed in the rACC, a comparable relationship between DLPFC activity and clinical outcome has not been observed. Thus, hypofunction of the rACC in patients who are less likely to respond to treatment may represent a neural marker of poor emotional coping resources. Patients who cannot draw on their implicit emotion regulatory reserves may benefit less from treatment.

Conclusion
Our understanding of the neurobiological abnormalities underlying many psychiatric disorders is rudimentary. Nevertheless, it is becoming clear that the pathophysiology of different psychiatric syndromes results from overlapping perturbations in specific brain systems. This observation challenges current psychiatric diagnostic practices, based as they are on discrete categorical constructs.

We have explored one perspective on the shared neurobiological substrates of disparate psychiatric disorders in detail: that of cognitive neuroscience. Examination of the normal function of various brain regions and circuits, through human lesion and neuroimaging studies and in animal models, produces a progressively refined understanding of regional brain function under normal circumstances. Functional abnormalities in these brain regions or circuits across distinct psychiatric disorders demonstrate how perturbation of normal brain function relates to specific domains of psychiatric phenomenology and endophenotypes. Such a circuit-level understanding of a disorder can have dramatic implications, as illustrated by the recent interest in invasive neurosurgical techniques for directly modulating brain function—such as by deep brain stimulation—for otherwise refractory psychiatric disease (Mayberg et al. 2005, Greenberg et al. 2006, Schlaepfer et al. 2007).

We have illustrated these principles with several well-characterized neural circuits, and shown how dysfunction of individual functional circuits can contribute to aspects of multiple different psychiatric disorders. This is hardly a complete catalog of brain regions and functions with which such a cognitive neuroscience perspective could be illustrated, nor is our treatment of the circuits and functions that we have described in any way comprehensive. Our purpose has rather been illustrative—to give examples of the utility of a cognitive neuroscience perspective and how it supports the idea that distinct neuropsychiatric conditions have biological commonalities.

This fact has important implications. It reinforces the now obvious truth that psychiatry must, as it advances, be informed by neuroscience, and that an understanding of the normal function of the brain is essential to comprehending how its perturbation can lead to disease. This perspective also illustrates how understanding the underlying biological substrates of psychiatric conditions can inform how we classify psychiatric symptomatology. Likewise, a biological understanding impacts how we view the relationship, both etiological and phenomenological, between disorders that we have previously considered distinct under the symptom-based, categorical nosology of DSM-III and DSM-IV-TR.

Ultimately, the exploration of biological commonalities among different psychiatric disorders, and of endophenotypes that are shared by different disorders, may present a major challenge to our current categorical diagnostic system. When the same neural systems are perturbed in two disorders, what is it that makes them distinct? Conversely, when symptomatically different conditions share underlying etiological factors, whence derives the difference in symptomatic presentation? Future diagnostic systems will have to reflect both the degree of biological relatedness across disorders and the biological and phenomenological differences between syndromes. In the future, we may diagnose psychiatric illnesses on new axes of genetic, environmental, and neural systems levels of analysis, resulting in unexpected groupings of disorders into new categories, spectrums, and dimensions of psychopathology.

Introduction
Advances in molecular and human genetics have led to the identification of nearly all of the genes underlying Mendelian diseases (i.e., those with clear-cut adherence to Mendelian law such as autosomal dominant, autosomal recessive, or X-linked). This progress has been revolutionary in terms of predicting disease risk (e.g., Huntington’s disease (Langbehn et al. 2004)), and understanding pathogenesis (e.g., familial hemiplegic migraine (Joutel et al. 1993) and Alzheimer’s disease (Hardy and Selkoe 2002)). The rapid success in identifying genes for Mendelian diseases generated the expectation that the same research strategies would eventually be successful in identifying genes for complex diseases, such as heart disease, obesity, cancer, diabetes and many common psychiatric conditions. However, the identification of genes for complex disorders has been more difficult, and few of the genes that have been identified through the candidate gene approach have withstood the test of replication (Altmuller et al. 2001, Ioannidis et al. 2001, Hirschhorn et al. 2002, Ott 2004a, Hirschhorn and Daly 2005).

The chief obstacles to identifying genes for complex diseases with the candidate gene approach include the lack of validity of phenotype characterization, biased sampling, inadequate controls, failure to correct for multiple tests, high false positive rate due to low a priori probability, use of an overly liberal alpha value, and the lack of adequate power of gene searching approaches (Todd 2006, Wacholder et al. 2000, 2004, Risch 2000).

Because of the failure to replicate of association studies of candidate genes, the genome-wide association method has been proposed as the most promising approach to gene identification in future studies of complex diseases (Botstein and Risch 2003, Hirschhorn and Daly 2005). The genome-wide association method that is based on a systematic search of equally spaced genetic markers across the genome with a comparison of cases to controls was demonstrated to have greater power than linkage (within family associations between genetic markers and disease) and association studies testing specified candidate genes between sibling pairs or between cases and controls (Risch and Merikangas 1996). The identification of a large set of common single nucleotide polymorphisms (SNPs) that capture much of the variation in the human genome and the advent of high throughput genotyping chips that can survey over 500,000 of these SNPs at a single pass, have enabled investigators to compare individual variation across large numbers of cases and controls. Whole genome association studies linking common SNPs, as well as copy number variations (CNVs) to vulnerability for complex disorders have become feasible. This approach has recently identified genes for macular degeneration (Klein et al. 2005, Edwards et al. 2005, Haines et al. 2005), and several other complex disorders including inflammatory bowel diseases (Duerr et al., 2006), diabetes (Field et al. 2007, Grant et al. 2006, Sladek et al. 2007, Groves et al. 2006), and prostate cancer (Freedman et al. 2006, Amundadottir et al. 2006). However, this approach has not yet led to gene identification for psychiatric disorders (Couzin and Kaiser 2007).

The first section of this chapter summarizes the background disciplines and approaches used to investigate genetic factors in mental disorders and reviews our current knowledge of the role of genetic epidemiology in mental disorders. The second section describes the approaches to gene identification and review the findings on specific genes...
underlying mental disorders. This review will focus on findings on schizophrenia and affective disorders, the two disorders that have been most widely investigated with the tools of both genetic epidemiology and molecular genetics.

**Genetic Epidemiology of Mental Disorders**

Kathleen R. Merikangas

**Genetic Epidemiology**

The substantial role of genetic factors underlying mental disorders was firmly established by the pioneering work of Räin, Böök, Sjögren, Angst, and Perris in Europe and Kallman, Heston, Rosenthal, Wender, and Kety in the US. Heston (1966) performed the first adoption study of schizophrenia, and found significantly higher rates of schizophrenia in adult offspring who had been adopted away from hospitalized schizophrenic mothers compared to offspring who had been adopted away from parents with no mental illness. The rates of schizophrenia in both groups approximated the rates expected in offspring who are reared by their biological parents. This result clearly implied that a substantial proportion of the increased risk of illness to biological offspring of schizophrenia mothers is independent of the rearing environment. Whether the mechanism of transmission of that risk was genetic or an effect of the prenatal environment could not be determined by this study. Heston's result was confirmed and extended by Rosenthal, Wender, and Kety in a series of publications beginning in 1968 that used a much larger sample of adopted away offspring of schizophrenics in Denmark. These studies demonstrated unequivocally that a substantial portion of the risk for schizophrenia is accounted for by the presence of the disease in birth parents independent of the rearing environment (Kety et al. 1976, 1978). In a second study, half-siblings were studied (Kety et al. 1987) in order to control for prenatal environment. These results indicated that genetics alone was responsible for a large proportion of the familial risk for schizophrenia.

During the latter decades of the last century, twin studies, which estimate the heritability of a disease by comparing the rates of concordance for the illness in monozygous versus dizygous twin pairs, became more common than adoption studies as a method of separating genetic from environmental risks for many psychiatric illnesses. At the same time, psychiatric genetics expanded from inpatient to outpatient settings, particularly in the US (Gershon and Cloninger 1994). With the introduction of epidemiologic research in psychiatry, systematic control groups were included in family studies and methods for incorporating population base rates and risk assessment were developed.

The field of genetic epidemiology examines the genetic and environmental causes of familial resemblance, and focuses on the role of genetic factors that enhance vulnerability or afford protection against disease. Genetic epidemiology employs traditional epidemiologic study designs to identify explanatory factors for aggregation in groups of relatives ranging from twins to migrant cohorts. Since epidemiology has developed sophisticated designs and analytic methods for identifying disease risk factors, these methods have been extended to include both genes and environmental factors as gene identification proceeds (MacMahon and Triopoulos 1996, Kuller 1979). In general, study designs in genetic epidemiology either control for genetic background while letting the environment vary (e.g., migrant studies, half siblings, separated twins) or control for the environment while allowing variance in the genetic background (e.g., siblings, twins, adoptees’-non-biologic siblings). Investigations in genetic epidemiology are typically based on a combination of study designs including family, twin and adoption studies.

**Family Studies**

Familial aggregation is traditionally the first source of evidence that genetic factors may play a role in a disorder. The common indicator of familial aggregation is the relative risk ratio, computed as the rate of disorder in families of affected persons divided by the corresponding rate in families of controls. The degree of genetic relatedness implies what proportion of genes is shared between a particular relative and an index family member or proband. First-degree relatives share 50% of their genes in common; second-degree relatives share 25% of their genes in common and third-degree relatives share 12.5% of their genes in common. Rates resemblance across first, second, and third degree relatives suggest possible patterns of genetic factors underlying a disorder. If familial resemblance is wholly attributable to genes, there should be a 50% decrement in disease risk with successive degrees of relationship from first to second to third. Likewise, diseases with strong genetic contributions tend to be characterized by 50% decrement in risk across successive generations. If the risk to second and third degree relatives decreases by more than 50% this suggests that either no single locus predominates in conferring disease risk, or that there may be a gene environment interaction or a more complex mode of gene transmission. This information can be used to derive estimates of familial recurrence risk within and across generations as a function of population prevalence. Specifically, the ratio of the rate of the disorder in relatives to a population-based rate ($\lambda$) is commonly used (Risch 1990). Whereas $\lambda$ tends to exceed 20 for most autosomal dominant diseases and those for which a single gene accounts for most of the risk, the range of values of $\lambda$ derived from family studies of many complex disorders tend to range from 2−5.

Besides suggesting possible patterns of genetic factors underlying disorders family studies may also provide evidence regarding etiologic or phenotypic heterogeneity. Phenotypic heterogeneity is suggested by variable expression of symptoms of the same underlying risk factors. On the other hand etiologic heterogeneity is demonstrated by common
manifestations of different etiologic factors between families. The family study method also permits assessment of associations between disorders by evaluating specific patterns of co-segregation of two or more disorders within families (Merikangas 1990).

**Twin Studies**

Twin studies which compare concordance rates for monozygotic twins (who share the same genotype) with those of dizygotic twins (who share an average of 50% of their genes in common) hold environmental influences constant. They thus provide the most direct estimates of the genetic contribution to the etiology of a disease phenotype. A rough estimate of the genetic contribution to the risk for a disorder is calculated by doubling the difference between the concordance rates for monozygotic and dizygotic twin pairs. Modern genetic studies employ path analytic models to estimate the proportion of variance attributable to additive genes, common environment and unique environment. There are several other applications of the twin study design that may inform our understanding of the roles of genetic and environmental disease risk factors. (1) Twin studies provide information on the genetic and environmental sources of sex differences in a disease, (2) Environmental exposures may be identified through comparison of discordant monozygotic twins, (3) Twin studies can also be used to suggest the genetic mode of transmission of a disease by inspection of the adherence of the decrement in risk between monozygotic and dizygotic twins to the mendelian ratio of 50%, (4) Twin studies may contribute to enhancing the validity of a disease through inspection of the components of the phenotypes that are most heritable. The twin family design is one of the most powerful study designs in genetic epidemiology not only because it yields estimates of heritability but also because it permits evaluation of multigenetrical patterns of expression of genetic and environmental risk factors. Recent updates of findings of twin studies of psychiatric disorders are available (e.g., Shih et al. 2004).

**Adoption Studies**

Adoption studies have been the major source of evidence regarding the joint contribution of genetic and environmental factors to disease etiology. Adoption studies either compare the similarity between an adoptee and his or her biological versus adoptive relatives, or the similarity between biological relatives of affected adoptees with those of unaffected, or control adoptees. The latter approach is more powerful because the potentially confounding effect of environmental factors is eliminated. Similar to the familial recurrence risk, the genetic contribution in adoption studies is estimated by comparing the risk of disease to biological versus adoptive relatives. These estimates of risk are often adjusted for the sex, age, ethnicity and other potential factors that may confound the links between adoption status and an index disease.

With the recent trends towards selective adoption and the diminishing frequency of adoptions in the US, adoption studies will be less feasible in identifying genetic and environmental sources of disease etiology (National Adoption Information Clearinghouse 2007). However, the increased rate of reconstituted families comprised of both siblings and half siblings may offer a new opportunity to evaluate the role of genetic factors in the transmission of complex disorders. Genetic models predict that half siblings should have a 50% reduction in disease risk compared to that of full siblings. Deviations from this risk provide evidence for either polygenic transmission, gene-environment interaction or other complex modes of transmission.

**Migration Studies**

Migrant studies are perhaps the most powerful study design to identify environmental and cultural risk factors. This study design has been used to study Asian immigrants to the US to demonstrate the strong environmental contributions to many forms of cancer and heart disease (Kolonel et al. 2004). One of the earliest controlled migrant studies evaluated rates of psychosis among Norwegian immigrants to Minnesota compared to native Minnesotans and native Norwegians (Lavik 1993). The study found a higher rate of psychosis among the immigrants compared to both the native Minnesotans and Norwegians. The results were ultimately attributed to a migration selection bias rather than an environmental exposure in the new culture. The application of migration studies to the identification of environmental factors is only valid if potential bias attributed to selection is considered.

**Genetic Epidemiology of Mental Disorders**

The wealth of data from family, twin, and adoption studies of the major mental disorders exceeds that of all other chronic human diseases. The increased recognition of the role of biologic and genetic vulnerability factors for mental disorders has led to research with increasing methodologic sophistication that has spanned the second half of the 20th century (Gershon et al. 1989, Weissman et al. 1986). There are numerous comprehensive reviews of genetic research on specific disorders of interest as well as on psychiatric genetics in general (Merikangas and Swendsen 1996, Shih et al. 2004, Kendler 1995, Tandon and McGuffin 2002, Tsuang et al. 2003).

Table 16–1 presents a summary of the relative risks (i.e., proportion of affected among first-degree relatives of affected probands versus those of relatives of controls) derived from controlled family studies of selected psychiatric disorders. The risk ratios comparing the proportion of affected relatives of cases versus controls are greatest for schizophrenia and bipolar disorder; intermediate for substance dependence and subtypes of anxiety, particularly panic disorder; and lowest for major depression. The estimates of heritability (i.e., the proportion of variance

</table>
attributable to genetic factors) are derived from twin studies, which compare rates of disorders in monozygotic and dizygotic twins. These findings reinforce the notion that genes play a major role in the extent to which mental disorders run in families. The heritability estimates for specific disorders shown in Table 16–1 are parallel to the risk ratios derived from family studies. Furthermore, adoption and half-sibling studies also support a genetic basis for the observed familial aggregation.

Schizophrenia

More is known about the genetic basis of schizophrenia than perhaps any other psychiatric disorder, with genetically-informative studies stemming from early in the last century. There are numerous reviews of this extensive body of research (Zerbin-Rudin 1980, Gottesman 1994, Kendler and Diehl 1993, Sullivan et al. 2003). Despite wide differences in methods, samples and geographic locations, controlled family studies yield a remarkably similar average relative risk of 8.9 to first-degree relatives. The role of genetic factors in the familial aggregation of schizophrenia is demonstrated by the four-fold greater concordance rate of schizophrenia in monozygotic compared to dizygotic twins found in the twelve studies to date. The average heritability in liability to schizophrenia across 12 studies is 0.81 (Sullivan et al. 2003).

Similarly, adoption studies using traditional paradigms and modern diagnostic criteria (if available) demonstrated that the average risk to first-degree relatives was 15.5% compared to 3.6% for controls, yielding a relative risk of 4.3.

Despite evidence regarding the importance of genetic risk factors for schizophrenia, the lack of expected mendelian risk ratios in the decrement in risk of schizophrenia as a function of genetic similarity suggests that schizophrenia is a genetically complex disorder (Risch 1990). Recent reviews of the genetic epidemiology of schizophrenia also converge in demonstrating the multifactorial etiology of this condition (Hallmayer 2000, Tsuang 2001, McGuffin 2004, Portin and Alalen 1997, Sullivan et al. 2003). The contribution of nonspecific environmental factors (i.e., multiple factors that may affect brain development) to schizophrenia’s etiology is implied by the largest and most recent cross-fostering study that showed that adoptive family environment was associated with schizophrenia spectrum disorders among genetically vulnerable individuals (Tienari et al. 2004).

Another important clue about potential environmental risk factors is the increased risk for the development of schizophrenia among immigrants in several different countries including East African immigrants to Sweden (Selten et al. 2002), Surinamese immigrants to the Netherlands (Hanoeman et al. 2002), Afro-Caribbean immigrants to the UK (Cooper 2005), Finnish immigrants to Sweden (Leao et al. 2006), and European immigrants to Canada (Smith et al. 2006). Although selective migration may be one explanation, there is converging evidence that socially disrupted environments may trigger the onset of schizophrenia in susceptible individuals.

An increased incidence of numerous neurodevelopmental abnormalities among children at high risk for the development of schizophrenia based on having an affected parent compared to offspring of parents without schizophrenia (Owens and Johnstone 2006, Brever et al. 2006) has led to a focus on early developmental factors in the etiology of schizophrenia. Some of the specific environmental risk factors currently under investigation include obstetric complications (Clarke et al. 2006), childhood trauma (Morgan and Fisher 2007), prenatal factors such as nutritional deficiencies (Ludvigsson et al. 2007), increased paternal age (Malaspina et al. 2002), family interactions (McGuffin 2004), maternal cytokines (Buka et al. 2001a), maternal infections (Buka et al. 2001b); gluten sensitivity (Kalaydjian et al. 2006), and cannabis use (Arseneault et al. 2002, Dean and Murray 2005). In summary, schizophrenia is now widely viewed as a neurodevelopmental disorder comprised of a confluence of vulnerability genes and environmental exposures (Dealberto 2007).

Mood Disorders

Mood disorders are comprised of a heterogeneous group of syndromes, of which major depression and bipolar disorder (manic-depression) are major subtypes. Bipolar disorder is one of the most widely studied psychiatric disorders from a genetic perspective (Sullivan et al. 2000, Merikangas and Yu 2002). Both major depression and bipolar disorder have important genetic components. Controlled family studies show a five-fold risk to relatives of major depression, and greater than a ten-fold risk to first-degree relatives of bipolar patients. The concordance rate for bipolar monozygotic twins is over five times that of dizygotic twins, and twin concordance for depression shows less dramatic but still notable differences. A summary of five methodologically comparable twin studies of major depression yielded an average estimate of the heritability of major depression of 0.37, with the remainder nearly totally attributable to environmental factors unique to the individual (i.e., 0.63) (Sullivan et al. 2000). The relative risks based on the few existing adoption studies also confirm that the familial recurrence cannot be attributed solely to environmental factors (Merikangas and Yu 2002).

The aggregate adoption study data on mood disorders reveal a moderate increase in rates of mood disorders among the biologic compared to adoptive relatives of adoptees with mood disorders (Faraone et al. 1990). With respect to bipolar disorder, there is little evidence for differential risk among biologic compared to adoptive relatives of adoptees with bipolar disorder. However, the small numbers of bipolar adoptees who have been studied (i.e., less than 50) do not provide an adequate test of genetic and environmental influences. The most compelling finding from adoption studies, however, is the dramatic increase in completed suicide among biological relatives of mood disorder probands (Mendlewicz and Rainer 1977).

Anxiety Disorders

At present, relatively few studies have examined anxiety disorders from the perspective of genetic epidemiology, and there is virtually no data from certain paradigms (such as adoption studies) (Carey and Gottesman 1981, Hettema et al. 2001). However, the existing research indicates that most anxiety disorders aggregate in families and several investigations have offered specific support for genetic etiology.

Panic Disorder

Of the anxiety subtypes, panic disorder has the strongest degree of familial aggregation. A review of 13 family studies
of panic disorder by Gorwood et al. (1999) shows a seven-fold relative risk of panic among relatives of panic probands compared to controls. In addition, early onset panic, panic associated with childhood separation anxiety, and panic associated with respiratory symptoms have each been shown to have a higher familial loading than other varieties of panic disorder (Goldstein et al. 1997). Although there has been some inconsistency reported by twin studies of panic disorder, recent studies using contemporary diagnostic criteria show that panic disorder has the highest heritability of all anxiety disorders at 44% (Kendler et al. 2001).

**Phobic States**

Though there are far fewer controlled family and twin studies of the other anxiety subtypes, all of the phobic states (i.e., specific phobia, agoraphobia) have also been shown to be familial (Fyer et al. 1995, Noyes et al. 1987, for review; see Merikangas and Angst 1995). The average relative risk of phobic disorders in the relatives of phobics is 3.1, with greater familial aggregation for the generalized subtype of social phobia. The heritability of phobias in twin studies is about 0.35% (Kendler et al. 1992).

**Generalized Anxiety Disorder**

There is also evidence for both the familial aggregation and heritability of generalized anxiety disorder in a limited number of studies (Newman and Bland 2006). The average familial odds ratio is approximately 5 (Mendlewicz et al. 1993, Noyes et al. 1987) and the heritability is 0.32 among female twin pairs (Kendler et al. 1992).

**Obsessive–Compulsive Disorder**

Controlled family studies of obsessive–compulsive disorder also reveal an elevated familial risk in probands with obsessive compulsive disorder compared to controls, with greater familial aggregation associated with early age of onset and obsessions rather than compulsions (Nestadt et al. 2000, Grabe et al. 2006, Pauls et al. 1995). However, twin studies of obsessive-compulsive disorder have yielded only weak evidence for heritability (Bellodi et al. 1992, Carey and Gottesman 1981, Lenane et al. 1990).

**Substance Use Disorders**

A positive family history of a substance use disorder is a consistent and robust risk factor for substance use outcomes in first-degree relatives (for comprehensive reviews of alcoholism see Heath et al. 1997, 2001, Tsuang et al. 2001, Merikangas 2002). Controlled family studies of alcohol use disorder reveal a three-fold increased risk of alcoholism and two-fold increased risk of drug abuse among the relatives of probands with alcoholism as compared to those of controls. Both alcohol abuse and dependence appear to be familial among females, whereas only dependence aggregates among the relatives of males with alcohol dependence (Merikangas et al. 1998a).

Twin studies have demonstrated the contribution of both genetic and environmental risk factors to both alcoholism and drug abuse (Kendler et al. 1994). Heritability of alcoholism (narrowly defined) has been estimated at 59% by some researchers (Kendler et al. 2000), while the heritability of problem drinking (using broad definitions) has been estimated at 8–44% in females and 10–50% in males (Heath et al. 1997). Several adoption studies conducted in Scandinavia demonstrated the importance of genetic factors underlying alcoholism (Goodwin 1985, Sigvardsson et al. 1996). Adoption study paradigms have shown not only that a disturbed adoptive family environment interacts with a genetic predisposition for alcoholism to affect the risk for the disorder (Cutrona et al. 1994), but that the adoptive family environment can predict alcohol abuse or dependence independent from genetic vulnerability (Cador et al. 1995). A recent “quasi-adoption” study that investigated the association between the biological family background (genetic factors), and a history of exposure to alcoholism during childhood (environmental factors) revealed greater effect of genetic risk factors among men than women, and common genetic and environmental risk factors contributing to alcohol dependence in both men and women (Light et al. 1996). The importance of environmental transmission of substance use disorders was demonstrated in a recent study of adoptive and step families (Newlin et al. 2000).

Although there has been less systematic research on the familial aggregation of drug use disorders, numerous family history studies and uncontrolled and controlled family studies have demonstrated that rates of substance use disorders are elevated among relatives of drug abusers compared to that of controls and population expectations (Bierut et al., 1998, Merikangas et al. 1998a). One controlled family study of drug use disorders using contemporary family study data (Merikangas et al. 1998b) showed an eight-fold increased risk of substance use disorders (opioids, cocaine, cannabis, and alcohol) among relatives of probands with drug disorders compared with relatives of psychiatric and normal controls. Family, twin, and adoption studies have also demonstrated common genetic and environmental factors that contribute to cannabis use disorders and other drug use disorders (Agrawal and Lynskey 2006). The results of numerous twin studies of substance use disorders in general, as well as those of specific drugs have shown that there are genetic factors underlying drug abuse in general (Kendler et al. 1999), as well as unique genetic factors associated with specific drugs of abuse including nicotine and cannabis (Kendler and Prescott 1998a, 1998b; Kendler et al. 2000, Tsuang et al. 2001).

**Complex Patterns of Transmission**

The application of advances in genomics to mental disorders is still limited by the complexity of the process through which genes exert their influence on mental disorders. There is substantial evidence that a lack of one-to-one correspondence between the genotype and phenotype exists for most of the major mental disorders. Phenomena such as penetrance (i.e., probability of phenotypic expression among individuals with susceptibility gene), variable expressivity (i.e., variation in clinical expression associated with a particular gene), gene-environment interaction (i.e., expression of genotype only in the presence of particular environmental exposures), pleiotropy (i.e., capacity of genes to manifest several different phenotypes simultaneously), genetic heterogeneity (i.e., different genes leading to indistinguishable phenotypes), gene-environment correlation (Dick et al. 2006) and polygenic and oligogenic modes of inheritance (i.e., simultaneous contributions of multiple genes rather than mendelian single gene models) are characteristic of the mental disorders, as they are of numerous...
other complex disorders for which susceptibility genes have been identified (Risch 1990). Other complicated situations include mitochondrial inheritance, imprinting, and epigenetic phenomena (Guttmacher and Collins 2002).

The high magnitude of comorbidity and co-aggregation of index disorders with other major psychiatric disorders (i.e., bipolar disorder and alcoholism, major depression and anxiety disorders, schizophrenia and drug dependence), in part induced by the classification system, has been demonstrated in both clinical and community studies (Merikangas 1990, Merikangas et al. 1998a, Maier et al. 1993, Maier et al. 2002). For example, alcoholism, a well-established complication of bipolar illness, may mask the underlying features of bipolarity, leading to phenotypic misclassification in genetic studies (Merikangas et al. 2007). Non-random mating is also a common phenomenon in mental disorders that impedes evaluation of patterns of familial transmission (Merikangas 1982). Assortative mating is particularly pronounced for substance use disorders for which substance dependence among spouses of substance dependent probands may be as high as 90% (Galbaud du Fort et al. 1998). These phenomena serve to decrease the signal to noise ratio in defining the mental disorders for genetic studies. Studies that attempt to identify the impact of these phenomena on phenotypic expression in individuals and families will bring us closer to understanding the role of the underlying genes on the components of mental disorders.

Future Applications of Genetic Epidemiology
The importance of epidemiology to the future of genetics has been described by numerous geneticists and epidemiologists who conclude that the best strategy for gene identification for complex disorders will ultimately involve large epidemiologic studies from diverse populations (Peltonen and McKusick 2001, Risch 2000, Khoury and Little 2000, Merikangas and Risch 2003). It is likely that population-based association studies will assume increasing importance in translating the results of genomics to public health. There are several reasons that population-based studies will be critical to the future of genetics. First, the prevalence of newly identified polymorphisms, whether SNPs or other variants, especially in particular population subgroups, is not known. Second, current knowledge of genes as risk factors is based nearly exclusively on clinical and non-systematic samples. Hence, the significance of the susceptibility alleles that have been identified for cancer, heart disease, diabetes, and so forth is unknown in the population at large. The next stage of research needs to move beyond samples of affected individuals to the general population in order to obtain estimates of the risk of specific polymorphisms for the population as a whole. Third, identification of risk profiles will require very large samples to assess the significance of vulnerability genes with relatively low expected population frequencies. Fourth, human genome epidemiology can provide information on the specificity, sensitivity, and impact of genetic tests (Khoury and Little 2000). Some of the areas where epidemiology can contribute to future genetic studies are described below.

Samples
The shift from systematic large-scale family studies to linkage studies in psychiatry has led to the collection of families according to very specific sampling strategies (e.g., many affected relatives, affected sibling pairs, affected relatives on one side of the family only, availability of parents for study, etc.) in order to maximize the power of detecting genes according to the assumed model of familial transmission. Despite the increase in power for detecting genes, these sampling approaches have diminished the generalizability of the study findings, and contribute little else to the knowledge base if genes are not discovered. Future studies will attempt to collect both families and controls from representative samples of the population in order to enable estimation of population risk parameters, enhance generalizability and examine the specificity of endophenotypic transmission.

Selection of Controls
The most serious problem in the design of association studies is the failure to select controls who are comparable to the cases on all factors except the disease of interest (Wacholder et al. 2000, Ott 2004b). Controls should be drawn from the same population as the cases, and must have the same probability of exposure (i.e., genes) as the cases. Controls should be selected to ensure the validity rather than representativeness of a study. Failure to equate cases and controls may lead to confounding (i.e., a spurious association due to an unmeasured factor that is associated with both the candidate gene and the disease). In genetic case-control studies, the most likely source of confounding is ethnicity because of differential gene and disease frequencies in different ethnic subgroups.

Risk Estimation
Because genetic polymorphisms involved in complex diseases are likely to be non-deterministic (i.e., the marker neither predicts disease nor nondisease with certainty), traditional epidemiologic risk factor designs can be used to estimate their impact. As epidemiologists add genes to their risk equations, it is likely that the contradictory findings from studies that have generally employed solely environmental risk factors, such as diet, smoking, alcohol use, etc., will be resolved. Likewise, the studies that seek solely to identify genes will also continue to be inconsistent without considering the effects of nongenetic biologic parameters, as well as environmental factors that contribute to the diseases of interest.

There are several types of risk estimates that are used in public health. The most common is relative risk, defined as the magnitude of the association between an exposure and disease. It is independent of the prevalence of the exposure. The absolute risk is the overall probability of developing a disease in an individual or in a particular population (Gordis 2000). The attributable risk is the difference in the risk of the disease in those exposed to a particular risk factor compared to the background risk of a disease in a population (i.e., in the unexposed). The population attributable risk relates to the risk of a disease in a total population (exposed and unexposed) and indicates the amount the disease can be reduced in a population if an exposure is eliminated. The population attributable risk depends on the prevalence of the exposure, or in the case of genes, the gene frequency. Genetic attributable risk would indicate the proportion of a particular disease that would be eliminated if a particular gene or genes were not involved.
For example, the two vulnerability genes for Alzheimer’s disease include the very rare, but deterministic genes β-amyloid precursor, presenilin-1, and –2, that signal a very high probability of the development of Alzheimer’s disease, particularly at a young age, and the susceptibility gene apolipoprotein-E ε-4 (APOE ε4) (Tol et al. 1999). The apolipoprotein-E ε-4 (APOE ε4) allele has been shown to increase the risk of Alzheimer’s disease in a dose-dependent fashion. Using data from a large multiethnic sample collected by more than 40 research teams, Farrer et al. (1997) reported a 2.6−3.2 greater odds of Alzheimer’s disease among those with one copy, and 14.9 odds of Alzheimer’s disease among those with two copies of the APOE ε4 allele. Moreover, there was a significant protective effect among those with the ε2/ε3 genotype. As opposed to the deterministic mutations, the APOE ε 4 allele has a very high population attributable risk because of its high frequency in the population. The APOE ε-4 allele is likely to interact with environmental risk and protective factors (Kivipelto et al. 2001, 2002). The population risk attributable to these mutations is quite low because of the very low population prevalence of disease associated with these alleles. This model of combination of several rare deterministic genes in a small subset of families and common genes with lower relative risk to individuals but high population attributable risk is likely to apply to many of the psychiatric disorders as well, and may in part explain some of the discrepancies in findings across studies to date.

Use of Endophenotypes for Classification
Numerous studies have begun to deconstruct psychiatric phenotypes by their component features or subtypes, including bipolar disorder (Benazzi 2007, Angst 2007), general anxiety disorder (Angst et al. 2006), obsessive compulsive disorder (Eappen et al. 2006), schizophrenia (Briffa et al. 2007, Gur et al. 2007), and panic disorder (Smoller and Tsuang 1998). Identification of phenotypic traits or markers, which are themselves heritable, and that may represent intermediate forms of expression between the output of underlying genes and the broader disease phenotype, have been termed “endophenotypes” (Gottesman and Gould 2003). Studies of the role of genetic factors involved in these systems may be more informative than studies of the aggregate psychiatric phenotypes since they may more closely represent expression of underlying biologic systems. To the extent that particular endophenotypes more clearly represent expression of genotypes, they may help to unravel the complexity of transmission of the mental disorders. For example, some of the endophenotypes that may underlie mood disorders include circadian rhythm, stress reactivity, and mood, sleep and appetite regulation (Lenox et al. 2002). However, before applying endophenotypes in gene identification studies, there should be evidence that the endophenotype has a stronger genetic signal than the broader phenotype. A recent meta-analysis of psychiatric endophenotypes (Flint and Munafò 2007) and a review of the genetic architecture of traits in model organisms do not provide evidence that endophenotypes are superior to current phenotypic disease definitions (Valdar et al. 2006).

Identification of Environmental Factors
Once susceptibility genes have been identified, it will be important to identify environmental factors that operate either specifically or non-specifically on those with susceptibility to mental disorders in order to develop effective intervention and intervention efforts. Langholz et al. (1999) describe some of the world’s prospective cohort studies that may serve as a basis for studies of gene-disease associations or gene-environment interactions. There is increasing evidence that gene-environment interaction will underlie many of the complex human diseases. Some examples include inborn errors of metabolism, individual variation in response to drugs (Nebert 1999), substance use disorders (Heath et al. 2001, Rose et al. 2000) and the protective influence of a deletion in the CCRS gene on exposure to HIV (Michael 1999).

However, few environmental exposures have been shown to have an etiologic role in mental disorders in prospective studies. Over the next decades, it will be important to identify and evaluate the effects of specific environmental factors on disease outcomes and to refine measurement of environmental exposures to evaluate specificity of effects. Study designs and statistical methods should focus increasingly on gene-environment interaction (Ottman 1990, Beatty 1997, Yang and Khoury 1997). Although numerous recent studies have reported gene-environment interaction between several genes that interact with nonspecific environmental exposures such as life stress, or childhood adversity and a range of outcomes including depression, cannabis dependence, and conduct disorder (Gillespie et al. 2005 Caspi et al. 2003), replication of these findings is still forthcoming (Ioannidis et al. 2001, Zammit and Owen 2006). Increased knowledge of the developmental pathways of emotion, cognition, and behavior will expand our ability to identify specific environmental factors such as infection, poor diet, prenatal environment, and early life experiences that interact with the genetic architecture of mood regulation and cognition (Meaney 2001).

Impact of Genomics on Psychiatric Science and Practice
Progress in genomics has far outstripped advances in our understanding of psychiatric phenotypes, and the complexity of their etiologies, as well as our current ability to identify genetic and environmental risk factors. Therefore, despite the extraordinary technical advances and availability of rapidly expanding genetic databases, the application of psychiatric genetic research to understand diagnostic heterogeneity, course and/or treatment outcome is still limited due to the lack of consistent findings of genetic studies to date. However, increasing understanding of the complex mechanisms through which genes exert their influence over the next decade should enhance the clinical utility of psychiatric genetics.

The goal of genomics research is ultimately prevention, the cornerstone of public health. Gaining understanding of the significance of genetic risk factors and learning proper interpretation of their meaning for patients and their families will ultimately become part of clinical practice, and clinicians will become increasingly involved in helping patients to comprehend the meaning and potential impact of genetic risk for nonpsychiatric disorders as well. As our knowledge of the role of genes in mental disorders advances, it will be incumbent upon clinicians to become familiar with knowledge gleaned from genetic epidemiologic and genomics research.
In the meanwhile, recurrence risk estimates from family studies constitute the best available knowledge on which to predict the risk of the development of mental disorders.

Identification of Genes Underlying Mental Disorders

Maria Karayiorgou

Linkage Studies

The traditional approach for locating a disease gene in humans is linkage analysis, which tests the association between DNA polymorphic markers and affected status within families. After linkage is detected with an initial marker, many other markers nearby may also be examined. Markers showing the strongest correlation with disease in families are assumed to be closest to the disease locus.

Linkage analysis uses DNA sequences with high variability (i.e., polymorphisms) in order to increase the power to identify markers that are associated with a disease within families. Historically, different methodological approaches have been applied. Earlier linkage studies employed Restriction Fragment Length Polymorphisms (RFLPs) (Botstein et al. 1980), whereas subsequent studies examined short tandem repeat markers, or “microsatellites,” (Weber et al. 1991) DNA sequences that show considerable variability among people but that have no functional consequences. More recently, linkage and association studies have examined SNPs (Risch and Merikangas 1996) to track diseases in families.

Markers in the candidate region identified by linkage analysis can be used to narrow the location of the disease gene through linkage disequilibrium (LD) analysis. LD is a population association between two alleles at different loci, and occurs when the same founder mutation exists in a large proportion of affected subjects in the population studied. Usually, the closer the marker is to the disease locus, the greater the proportion of affected subjects who carry the identical allele at the marker (Risch 2000). However, in measuring the strength of LD for a given marker, it is also important to select unaffected control subjects from the same population, because an allele shared among affected subjects may also be common in the general population and thus shared by chance rather than due to proximity to the disease locus (Risch 2000).

For complex human diseases, a simple mode of genetic inheritance is not apparent, and indeed, multiple contributing genetic loci are likely to be involved. Study designs that do not depend on the particular mode of inheritance are required for linkage analysis. Since affected relatives provide most of the information for such analyses, studies that focus on searching for increased sharing of marker alleles above chance expectation among affected relatives may be employed. The simplest of such studies involves affected sibships, where allele sharing in excess of 50% (the expectation when there is no linkage) is sought.

Association Studies

Linkage analysis has not proven successful in identifying genes for most complex diseases, presumably because the effects of the underlying genes are not strong enough to be detected by linkage (Risch and Merikangas 1996). Therefore, genome-wide association studies have been offered as a more powerful approach. Completion of the human genome project has provided an unprecedented opportunity to identify the effect of gene variants on complex phenotypes, such as psychiatric disorders. Functional genomics technology involving microarrays and proteomics will provide added insights regarding gene function on the cellular level, improving our ability to predict phenotypic effects of genes at the organismic level (Risch 2000). The recently proposed project (known as the HapMap project) to develop a map of human haplotypes, or blocks of genes that may have been conserved in evolutionary history, has generated considerable enthusiasm for its potential to inform the genetic basis of complex disorders in the general population. There has been considerable discussion regarding the value of studying SNPs with functional significance versus non-coding or evenly spaced SNPs. Botstein and Risch (2003) propose that the initial work employ sequence-based association studies that focus on functional coding regions rather than a map based approach (Collins et al. 1997, Gabriel 2002) that relies solely on the location of haplotypes in order to maximize power and efficiency for detecting genes for complex human diseases.

Association studies generally examine candidate genes among affected individuals and unrelated unaffected controls. The same limitations that apply to case-control studies of other risk factors must also be considered in genetic case-control studies. The most serious problem in the design of association studies is the failure to select controls who are comparable to the cases on all factors except the disease of interest. Failure to equate cases and controls may lead to confounding (i.e., a spurious association due to an unmeasured factor that is associated with both the candidate gene and the disease). In genetic case-control studies, the most likely source of confounding is ethnicity because of differential gene and disease frequencies in different ethnic subgroups. Aside from confounding, association studies are particularly prone to false positive findings due to multiple testing without correction and the low prior probability of a gene-disease association (Wacholder et al. 2004). In addition, there is a strong publication bias against reports of negative association studies (Ioannidis et al. 2001). The former problem can be resolved in part by the use of much higher α levels (i.e., false positive error rates) in association studies (Wacholder et al. 2000).

Application of Linkage and Association Studies in Psychiatry

Based on the dramatic advances in molecular genetics during the past 20 years as described above, there has been a
major shift in the focus of psychiatric genetic investigations during the past decade from elucidating patterns of familial transmission to localizing genes underlying mental disorders using linkage studies and association studies (McInnes and Freimer 1995). Although there remains controversy regarding what constitutes replications of genetic findings for several mental disorders, there are several recent promising findings in psychiatric genetics, and the outcome of several large genome wide association studies of mental disorders will soon be available. In addition, the increasing tendency for collaborative efforts on genetics studies within psychiatry may yield greater power to detect genes of small effect. In fact, the success of this approach has already been demonstrated as described above.

**Systematic Follow-Up of Linkage Signals**

In schizophrenia, more than 20 genome-wide linkage scans aiming to localize genes have been reported thus far. Two meta-analyses have also taken place (Lewis et al. 2003, Badner and Gershon 2002). The goal of such meta-analyses is to examine the combined results of several genome-wide scans to clarify inconsistencies among individual studies and detect signals that may have been missed in individual studies (meta-analytic approaches tend to amplify signals that are weak but consistent among studies and attenuate ones that are strong but non-reproducible). The first meta-analysis study confirmed 8p, 13q, and 22q as valid linkage regions, likely containing one or more susceptibility gene. The second meta-analysis study (using a different statistical methodology) implicated 2p12–q22.1 (under stringent criteria), as well as loci at 5q, 3p, 11q, 2q, 1q, 22q, 8p, 6p, 20p, and 14q (under less stringent thresholds). It would appear that approximately ten regions of the genome are likely to contain schizophrenia susceptibility genes, although this is almost certainly an underestimate because (a) meta-analytic approaches tend to attenuate true strong signals that are population specific and (b) it is expected that many schizophrenia susceptibility genes will be undetectable by linkage studies. The ultimate validation of the linkage results will be the identification of the susceptibility genes themselves. For some of the loci described above, systematic fine-mapping efforts were undertaken. These systematic efforts employ genotyping of relatively large numbers of markers, including SNPs and LD assays in family-based or case-control samples and have resulted in the identification of strong positional candidate genes (Gogos and Gerber 2006, O’Tuathaigh et al. 2007). To date, at least 10 genes have been identified through systematic follow-up of linkage signals in schizophrenia (see Table 16–2 for a list of these genes, as well as their possible biological functions).

Similar to schizophrenia, previous linkage studies and meta-analyses have implicated several genomic loci in bipolar illness as well (Segurado et al. 2003). Dense mapping and search for a causative mutation in these loci is currently in progress but the results have not been as forthcoming as in schizophrenia. For example, Barden and colleagues (2006) examined over 3 candidate genes at 12q24.3 and found nominal association in bipolar families with a non-synonymous SNP at the P2RX7 gene, a purinergic ligand-gated ion channel. This Gln460Arg polymorphism occurs at an amino acid that is conserved between humans and rodents and is located in the C-terminal domain of the receptor, known to be essential for normal P2RX7 function. Blair et al. (2006) examined 17 brain-expressed genes on 4p35 and found that

*In chronological order of appearance of the reports until August 2006.
the haplotype extending over the \textit{FAT} gene, encoding a cadherin family protein, is associated with bipolar disorder in four independent sample sets. They also found that lithium treatment in mice down-regulates the \textit{FAT} gene, and concluded that this gene confers a genetic risk for bipolar disorder.

Notably, several common regions have been implicated in linkage genome scans for bipolar illness and schizophrenia, which has led to the formulation of the hypothesis that the two disorders share some susceptibility genes. Indeed, the \textit{G72} gene on chromosome 13q and the \textit{DISC1} gene on chromosome 1q (Table 16–1) have been associated with genetic risk for both schizophrenia and bipolar illness.

Compared to schizophrenia and bipolar disorder, efforts to systematically identify positional susceptibility genes for other major and common psychiatric disorders, such as major depression, are lagging. This may be due to higher phenotypic or genetic heterogeneity or to the contribution of environmental factors that confounds the effort to identify genetic factors. Despite these potential limitations, the number of reports of large-scale linkage studies of depression is increasing. Implicated genomic regions include 1p36, 1q23.3-q24.11, 13q31.1-q31.3, 15q25.3-26.2, 3p12.3-q12.3 and 18q21.33-q22.2 and there is some evidence for convergence of linkage findings across studies, but more data are needed to permit meta-analysis (Levinson 2006).

Interestingly, some of these regions overlap with those implicated in bipolar disorder and it was recently shown that the non-synonymous coding SNP in the \textit{P2RX7} gene previously found to be associated with bipolar disorder (see above), was significantly associated with major depression as well (Lucae et al. 2006).

It should be emphasized that, even for the stronger genetic findings, it is too early to draw firm conclusions about their generalization among different samples and populations. Even for genes where association signals have been observed in several “replication” studies, a critical review of the literature would reveal issues with the extent of coverage of the implicated loci, consistency of the risk allele or risk haplotype across studies, or structure of the samples used in the original and replication studies. In addition, publication bias against negative reports can also provide a false picture of the overall available data. While these issues are relevant to all common, complex disorders, they are likely to be more pronounced in genetic studies of psychiatric disorders, which are confounded by a larger degree of phenotypic heterogeneity.

One way to evaluate the data and assess the degree of significance of the findings described above is to use a combination of criteria that include the degree of statistical significance, the reproducibility of the associations in independent samples, the identification of independent rare risk alleles and the consistent findings from animal model studies and endophenotype-based studies in humans. Based on these criteria, support for at least some of the genes shown in Table 16–2 (such as \textit{PRODH}, \textit{DTNBP1}, \textit{NRGI}, \textit{G72}, or \textit{DISC1}) appears to be quite strong. However, a recent study evaluating the evidence supporting the dysbindin (\textit{DTNBP1}) gene (Mutsuddi et al. 2006) is particularly didactic and has raised some important general concerns. \textit{DTNBP1} was first identified as a putative schizophrenia-susceptibility gene in Irish pedigrees, with a report of association to common genetic variation (Gogos and Gerber 2006). As is the case with many genes in Table 16–2, several replication studies have claimed confirmation of an association to this gene in independent European samples, but the reported risk alleles and haplotypes appear to differ between studies. To facilitate evaluation of existing evidence of association for this gene, Mutsuddi et al. (2006) genotyped all associated SNPs reported in the original and replication studies in a reference control sample. Using this high-density reference map, they compared the putative disease-associated haplotype from each study and found that the original and replication studies are inconsistent with regard to the identity of the disease-associated haplotype at \textit{DTNBP1}. The authors further demonstrated that, in all studies, the European-derived populations studied have haplotype patterns and frequencies that are consistent with HapMap samples (and each other), rendering it therefore unlikely that population differences are creating the inconsistency of the association studies. The authors concluded that evidence of association for \textit{DTNBP1} is, at present, equivocal and unsatisfactory. This may also be applicable to other genes in Table 16–2 for which similar patterns of association were observed and unless a definition of replication, which is strict and precise is implemented, false positive findings may propagate and confuse the literature (Sullivan 2007).

\textbf{Candidate Gene Approaches}

Genes are considered candidates for a psychiatric disorder based usually on their function (in the context of perceived deficits in disease pathophysiology) or genomic location (in the context of linkage signals or chromosomal abnormalities). Indeed, the most active area in molecular genetic research of psychiatric disorders is replication studies of previously reported candidate genes and analysis of related genes. As a result, the list of candidate genes is extensive and rapidly growing. Listing all the candidate genes is beyond the scope of this chapter, but a reasonably complete and regularly updated list of candidate genes can be found at http://geneticassociationdb.nih.gov Table 16–3 shows the genetic data for a small subset of candidate genes that are either located in the general vicinity of linkage signals or identified through multi-pronged candidate gene approaches that produced convergent genetic and biological evidence, or both (Gogos and Gerber 2006, O’Tuathaigh et al. 2007).

Despite the burgeoning nature of the candidate gene research most replication studies do not support the initial positive findings. There are several good reasons for that, some of them described by Freimer and Sabatti (2004). For example, “too much testing,” that is, testing of many variants without the appropriate corrections for the number of performed tests, can lead to false positive findings, whereas “too little testing,” that is, failure to test exhaustively the entire genetic variation in a given locus, can lead to false negative findings. Possibly the most important issue is that of the prior probability of association of a trait to a single candidate gene. If one makes the conservative simplifying assumption that the gene was picked at random from the approximate 30,000 genes in the genome, the prior probability that a given candidate gene is associated with a trait is approximately 1/30,000. Almost no candidate gene association study meets this threshold and usually,
investigators implicitly assume that meaningful prior evidence guides the selection of a candidate gene (i.e., that the prior probability of association is higher than 1/30,000). However, for association studies, there is no form of prior evidence that can be readily quantified in a probability and therefore estimates of prior probability are inherently subjective. As a result, stringent cut-offs for gene association studies are not usually applied in the majority of genetic publications, so that many of even the most highly publicized results are probably false positives.

Nevertheless, a number of interesting candidate genes have emerged (Table 16–3) and intriguingly some of the most interesting candidates are located in the general vicinity of linkage signals. Although far from proven, the recurrent observation of clustering of candidate susceptibility genes could indicate that more than one gene could contribute to at least some of the linkage signals in psychiatric disorders. This is not surprising since linkage “peaks” are large, often spanning tens of millions of base pairs and hundreds of possible genes. Interestingly, recent efforts to fine-map Quantitative Trait Loci (QTL) peaks in simpler organisms (analogous to linkage peaks in human studies) have shown that often an apparently single QTL fractionates into multiple tightly linked QTLs. For example, Yalcin et al. (2004) have fine-mapped in the mouse a QTL shown to influence anxiety-related behaviors and found that it fractionates into three discrete peaks. Therefore, the task of fine-mapping specific susceptibility genes under linkage peaks in humans, where we have fewer and less powerful approaches than in model organisms, may be even more difficult than we have previously estimated. It is likely, for example, that some of the genes described in Table 16–2 may not account for the entire linkage signal and that linkage studies may have substantially underestimated the number of loci that are involved in any of the mental illnesses.

**Fine Mapping of Genomic Rearrangements**

**Isolated De Novo and Familial Chromosomal Abnormalities**

Both de novo and familial chromosomal abnormalities have been described in patients with psychiatric or neurological conditions, but only a small proportion of these have been studied at the molecular level. One example is that of a large Scottish family in which there is a highly significant co-

segregation (LOD > 7) between major mental illness and the presence of a balanced translocation between chromosomes 1 and 11. The DISC1 gene is directly disrupted by the chromosome 1 breakpoint (Millar et al. 2000) and subsequent supportive evidence for its involvement in schizophrenia and bipolar disorder has come from linkage and case–control association studies on karyotypically normal populations (Gogos and Gerber 2006, O’Tuathaigh et al. 2007).

It has been suggested that DISC1 is involved in neurological development particularly within the cerebral cortex, and that loss of DISC1 function might underlie neurodevelopmental dysfunction in schizophrenia and other psychiatric disorders (Kamiya et al. 2005). Based on in vitro observations that phosphodiesterase 4B (PDE4B) and DISC1 physically interact, Millar et al. (2005) proposed an alternative model of DISC1 action involving regulation of cAMP signaling, a second messenger system known to modulate affect and cognition. Recently, Koike et al. (2006) attempted to mimic the effects of the chromosomal translocation observed in the Scottish family using a gene-targeting approach designed to generate a truncated Disc1 transcript, and possibly protein. C57BL/6J mice carrying a debilitated Disc1 allele demonstrated a deficit in spatial working memory performance, which is often affected in patients with schizophrenia and their unaffected relatives. This deficit was observed in both heterozygous and homozygous mutant mice, although neither showed any changes in locomotor activity or PrePulse Inhibition (PPI).

Analysis of further cytogenetic abnormalities in schizophrenic patients have identified additional genes, such as PDE4B (Millar et al. 2005), NPA3 (Kammasaran et al. 2003), GRIK4 (Pickard et al. 2006) and GRIA3 (Gecz et al. 1999) as potential candidate genes, but in most of these cases convergence of supportive genetic evidence from karyotypically normal patient populations and from animal model studies is still lacking. Interestingly, mice bearing inactivating mutations in the genes encoding the Npas1 and Npas3 transcription factors have been shown to exhibit a spectrum of behavioral and neurochemical abnormalities and adult brain tissues from Npas3- and Npas1/Npas3-deficient mice exhibited a distinct reduction in reelin, a large, secreted protein whose expression has been reported to be attenuated in postmortem brain tissue of some patients with schizophrenia and other neuropsychiatric disorders (Erbel-Sieler et al. 2004, Brunskill et al. 2005).
Copy Number Repeat Variations

CNVs are 21-kb DNA segments that are present in variable copy number in comparison to a reference genome. Recently, a detailed CNV map of the human genome has emerged (Redon et al. 2006, Sebat et al. 2004). Redon et al. (2006) analyzed 270 individuals from 4 distinct populations with ancestry in Europe, Asia, or Africa and described a total of 1,447 CNVs covering 12% of the total genome (~360 megabases of DNA). Though the vast majority of CNVs were found outside of coding sequences, thousands of putative functional segments of DNA fall within CNVs and 99% of them overlap with conserved non-coding sequences. In addition, at least 10% of disease-related genes in the Online Mendelian Inheritance in Man (OMIM) database are associated with CNVs. As this may be only a fraction of the number that will eventually be uncovered, the data suggest that CNVs may represent the greatest source of human genetic diversity.

The implications of these findings in the genetic basis of psychiatric disorders will become clear in the next few years. Psychiatric research already has one extensively studied example of a relatively rare CNV (the 22q11 microdeletion, Karayiorgou and Gogos 2004) and probing for additional more common CNVs may prove to be the next frontier in psychiatric genetics. Indeed, CNVs were found in the PRODH, DISCI, CAPON, ETH, and some of the other leading susceptibility genes described in Table 16–2.

Iterative Human and Mouse Genetic Approaches

Mouse models of “susceptibility genes” hold considerable promise not only in understanding the function of a gene and its contribution to disease pathogenesis and pathophysiology, but also in additional gene discovery. In order to create accurate genetic mouse models of psychiatric disorders, the functional nature of any genetic variant associated with the disease must be taken into account (Arguello and Gogos 2006). Unfortunately, in the case of complex genetic disorders, the associated variants usually have no obvious effect on protein structure. Given this limitation, genetic mouse models have been limited, for the most part, to constitutive or conditional knock-outs, although a few mouse models have also appeared that actually attempt to mimic the functional outcomes of rare genetic variants associated with psychiatric disorders (Arguello and Gogos 2006).

Animal models of psychiatric disorders (including schizophrenia) are traditionally analyzed through behavioral assays, but mechanistic insights into the nature of the deficit under investigation cannot be achieved by behavioral assessment alone. Rather, a combined approach that begins at the behavioral level and culminates at the cellular and molecular levels is needed. Approaches at the molecular level have two important advantages. First, molecular functions of a gene are more likely to be evolutionarily conserved compared to any behavioral outcomes the gene may influence. Second, it is conceivable that the “closer” one probes to the primary deficit, the less likely it is that downstream compensatory mechanisms come into play and the more likely that any resulting functional consequences will be detectable. Molecular level approaches in particular can be used to identify (in a high-throughput fashion) changes in gene expression, protein levels, or post-translational modifications underlying the consequences of specific genetic disruptions, thus facilitating in vivo identification of physiologically relevant genes, gene pathways and cellular processes that either serve as direct targets, or interact with the disrupted pathways to modulate susceptibility to a given psychiatric disorder (Lai et al. 2006). Indeed, recent work in genetic mouse models suggests that some changes in gene expression induced by a mutation could be adaptive in nature and could reduce the penetrance of the primary mutation (Arguello and Gogos 2006). The involvement of these genetic pathways can be verified in follow-up human genetic studies.

The power of such iterative human and mouse genetic approaches was recently demonstrated in a series of studies designed to understand the dramatically enhanced risk for schizophrenia (20–30 fold increase) associated with a heterozygous microdeletion of chromosome 22q11.2 (22q11DS) (Paterlini et al. 2005). Next to having two schizophrenic parents or an identical twin with schizophrenia, a microdeletion in the q11.2 locus of chromosome 22 is the highest known risk factor, genetic or environmental, for schizophrenia (Karayiorgou and Gogos 2004). PRODH is a leading candidate gene from the 22q11.2 locus identified initially through human genetic studies in families afflicted with schizophrenia. It encodes a mitochondrial enzyme that metabolizes L-proline, a putative neuromodulatory amino acid that may influence glutamatergic transmission (Gogos and Gerber 2006, O’Tuathaigh et al. 2007). A Prodh mutant mouse strain that represents an accurate model of the functional consequences of susceptibility variants described for this gene has been established and shows many neurochemical and behavioral features relevant to schizophrenia. Specifically, Prodh deficiency caused increased cortical dopamine efflux in mutant mice following acute, systemic amphetamine (AMPH) administration. Prodh-deficient mice also show hypersensitivity to the locomotor effects of AMPH, abnormal PPI and deficits in associative learning. Deficits in a spatial working memory task emerged in Prodh-deficient, but not wild-type, mice only upon pharmacological inhibition of Comt, an enzyme involved in degradation of dopamine and encoded by a schizophrenia candidate gene also located within the 22q11.2 microdeletion locus, revealing a previously unsuspected interaction between these two genes. This interaction was also reflected at the transcriptional level, with levels of Comt transcript and protein upregulated in the frontal cortex of Prodh-deficient mice. This seems to represent a homeostatic response, whereby an increase in Comt expression is engaged to buffer excessive dopamine signaling in the frontal cortex of mice with a hypomorphic variant of the Prodh gene (Paterlini et al. 2005). Based on these observations it was speculated that individuals with schizophrenia who have a 22q11.2 deletion are at a particular disadvantage because they are deficient for both genes and perhaps unable to compensate efficiently, through COMT, for the cortical dopaminergic hyperactivity induced by PRODH deficiency. This may explain, at least partly, the high risk for schizophrenia associated with 22q11DS. Because the COMT gene comes into primarily two forms (O’Tuathaigh et al. 2007), one low activity (Met-COMT) and one high activity (Val-COMT), one expectation of this model is that hyperprolinemic 22q11DS subjects carrying the deletion on one chromosome and the Met-COMT low activity allele in their non-deleted copy are at higher risk for psychosis. Raux
et al. 2007 tested this prediction in a sample of 92 adult or adolescent subjects with 22q11DS. They found, as predicted from the mouse model, that hyperprolinemic 22q11DS subjects bearing the Met-COMT low activity allele are indeed at higher risk for psychosis. In addition to demonstrating the power of genetic mouse models, these findings produced by iterative human and mouse genetic approaches have important potential therapeutic consequences for subjects with 22q11 microdeletions and schizophrenia.

Genetic Studies of Endophenotypes
In evaluating the significance of the genetic findings described thus far, with the exception of the 22q11 microdeletions, one is puzzled by the small odds ratios that have been assigned to any given association between individual genes and psychiatric illnesses. These range largely from 1.1 to 1.5, as shown in several meta-analyses of functional candidate gene association studies and early results from positional candidate genes (Kendler 2005). Given our expectation that the first set of effects detected in any research area tend to be the most robust, it is perhaps likely to expect that any additional genes that will be discovered for psychiatric disorders will have smaller average effects than the genes found thus far.

In that context, it is widely believed that use of endophenotypes holds promise in making the mapping of candidate genes for the complex phenotype more successful. By “endophenotypes” or “intermediate phenotypes” we usually refer to heritable quantitative traits that mediate the disease phenotype and can serve as biological markers (Gottesman and Gould 2003). The expectation is that use of endophenotypes can reduce the heterogeneity and largely subjective nature of a qualitative psychiatric diagnosis by utilizing traits that are quantitative, more objectively measured and, hopefully, simpler in their genetic architecture. There is also the common assumption that the effect sizes of genetic loci contributing to endophenotypes are larger than those contributing to disease susceptibility, thus increasing the chance that genetic linkage and association tests will detect them. As a result, the endophenotype concept emerged as a potential strategy for characterizing the neural systems affected by risk gene variants to elucidate quantitative, mechanistic aspects of brain function implicated in psychiatric disease. However, as described above, before proceeding with the application of endophenotypes in association studies of mental disorders, it will be important to demonstrate their superior to current phenotypes for mental disorders (Flint and Munafò 2007, Valdar et al. 2006).

FUTURE DIRECTIONS OF GENE DISCOVERY

Gene Discovery Via Genome-Wide Association Studies
As described above, large-scale association studies using maps of anonymous and common SNPs have been promoted as the tool that will accelerate the discovery of genes related to common diseases (Maraganore et al. 2005, Herbert et al. 2006). This approach is not without limitations, however. For example it has, by design, low power to detect the effects of rare variants, which are poorly tagged by common SNPs. In addition, it remains unclear whether reproducible but small effect (OR < 1.25) common genetic variants potentially involved in complex psychiatric diseases will be readily detectable by such large-scale association testing approaches. Despite these and other statistical hurdles, genome-wide association studies, if appropriately performed and interpreted, promise to expand considerably our knowledge of the genetic basis of psychiatric disorders.

In-Depth Probing of Gene–Gene Interactions
It is widely believed that genetic interactions among susceptibility genes (especially epistasis, a phenomenon whereby the effects of a given gene on a biological trait are masked or enhanced by one or more other gene) lie at the core of their complexity. By utilizing statistical models to risk of illness in various classes of relatives, Risch (1990) has suggested that gene-by-gene interactions are important in the etiology of schizophrenia. However, such interactions have been studied very little, primarily because twin and adoption studies, which would be normally employed, are very weak at detecting such effects (Neale et al. 1994). The biological basis of these epistatic interactions thus remains largely elusive in psychiatric disorders, but recent studies have provided some important relevant insights (Paterlini et al. 2005, Millar et al. 2005). The Paterlini et al. study, which is also described earlier, is particularly instructive because it indicates that patterns of genetic interactions that involve impaired synaptic function and impaired homeostasis or compensation (genomic buffering) might also account for the epistatic component of the genetic risk of psychiatric disorders in general. The Millar et al. study did not explicitly address the pattern of interaction at the organism level, but used the two-hybrid system to identify a molecular interaction between the products of two schizophrenia candidate genes, the DISC1 protein and (PDE4B) (Millar et al. 2005). Although the gene encoding for PDE4B is not included in the list of strong candidate genes outlined earlier, the authors showed it is disrupted by a balanced translocation in a subject diagnosed with schizophrenia and a relative with chronic psychiatric illness. The PDEs inactivate cAMP, a second messenger implicated in learning, memory, and mood. It was shown that DISC1 interacts with the UCR2 domain of PDE4B and that elevation of cellular cAMP leads to dissociation of PDE4B from DISC1 and an increase in PDE4B activity. The authors proposed a genetic interaction model whereby DISC1 sequesters PDE4B in resting cells and releases it in an activated state in response to elevated cAMP.

Statistical methods of analysis designed to probe epistasis are clearly of growing importance in the genetic dissection of complex disorders. Currently, a variety of methods exist to detect or control for the presence of epistasis. However, all the difficulties with association studies of the main effect of genes (such as low a priori probabilities and multiple testing) are further exacerbated in studying interactions. In addition, these methods are limited by the need for large sample sizes that ensure adequate power to detect gene interactions. An accumulating number of association studies have reported interactions, but none of these studies have yet been widely replicated. For example, Hennah et al. (2007) conditioned their sample of Finnish families for the presence of the Finnish tentative risk allele for DISC1, and re-analyzed their genome-wide scan data
of 443 markers based on this stratification. Two additional loci displayed evidence of linkage (lod > 3), and included a locus on 16p13, proximal to the gene encoding NDE1 that has been previously shown to bind DISC1. Although none of the observed linkages remained significant after multiple test correction through simulation, further analysis of NDE1 revealed a suggestive association between variation in the NDE1 gene and schizophrenia specific to females. This finding awaits replication, but overall it supports the concept that initial gene findings in multifactorial diseases will assist in the identification of other components of complex genetic etiology.

In general, direct biological inference from the results of statistical tests is very difficult because statistical interaction does not necessarily imply interaction at the biological level. In all, the degree to which statistical modeling can provide insights into the underlying disease mechanisms is likely to be limited, and might require prior knowledge of the underlying etiology. The question of true biological interaction remains of extreme importance in the field of complex psychiatric genetics, but might ultimately be better answered primarily via a combination of molecular and animal model-based approaches.

**Implications for Understanding Disease Pathophysiology and for Improving Treatment**

What are the implications of the genetic findings obtained thus far for our understanding the disease pathophysiology? If we use schizophrenia as an example, there are two major pharmacological hypotheses regarding the pathophysiology of this disease—the dopaminergic and glutamatergic hypotheses (Seeman 1987, Coyle 1996). The two hypotheses are not incompatible as it is likely that primary changes in one system would lead to associated alterations in the other.

Efforts for synthesis of the initial genetic findings in the context of specific neurotransmitter systems have been reported (for example, Moghaddam 2003). However, it might be premature at this point to claim that the existing genetic data support the critical involvement of one neurotransmitter system over another. For one thing, the genes identified thus far (see for example Tables 16–2 and 16–3) are involved in several neurotransmitter systems. For some of them (such as PRODH, G72, DTNBPI, NRG1, ZDHHC8, CAPON) there is variable degree of experimental evidence that they are involved in excitatory glutamatergic pathways, while for others, there is clear evidence of involvement in dopamine (COMT, AKT1), GABA (5q GABA receptor cluster, AKT1), or trace amine signaling (TAAR6). However, even for genes that primarily act via disruption of excitatory synaptic function, the final effect could be mediated by abnormal dopamine signaling. In addition, several of the hypotheses regarding the function of the candidate genes have not been sufficiently tested and may be inaccurate (for example the function of G72 as a DAO activator and modulator of NMDA signaling has been recently questioned). Finally, many of the genes appear to have pleiotropic effects that are not restricted to a particular type of synaptic transmission and involve several aspects of neuronal biology. Thus, it is too early to determine from the existing genetic evidence what neurotransmitter systems might be primarily affected in the disease. Indeed, at this juncture, it is equally probable that the cumulative effect of the risk variants will emerge from the pattern of expression and the pattern of interaction among these genes, and it could be restricted to specific brain regions, specific cell types, or both, rather than specific neurotransmitter systems. This spatial selectivity could underlie the differences and commonalities among common psychiatric disorders, as well as their distinction from other common and serious CNS conditions, such as mental retardation, or epilepsy that employ common neurotransmitter systems.

Understanding the function and the interactions among individual susceptibility genes could eventually lead to the design of highly effective targeted therapies for patients with fewer side effects. However, in simpler genetic conditions where knowledge of the genes and protein alterations is often available it has proven highly challenging to translate this genetic knowledge into creation of therapies. Although optimism should perhaps be tempered by this experience, it is conceivable that despite their more complex etiology, multifactorial disorders like schizophrenia may be more amenable to mechanism-based therapeutic intervention (Gogos and Gerber 2006): disease risk associated with common small effect genetic variations is usually very low, but because the risk alleles are so common, a low disease risk corresponds to a large population attributable risk (which means that if the population were monomorphic for the non-risk allele, the prevalence of the disease would be considerably lower). Thus, as noted before, directed therapies might only need to provide relatively modest modulation of appropriate molecular targets to reach an effective threshold in a large fraction of patients, in contrast to simple conditions, where compensation for more pronounced functional alterations might be required.

Further Reading

Introduction
For the past 60 years, the predominant strategy for developing treatments for psychiatric disorders has depended on the discovery of a prototypical treatment through serendipity, or “trial and error” (Berton and Nestler 2006, Gould et al. 2004, Jacobsen 1986). Research efforts would then be focused on the neurobiological actions of the discovered treatment, with the goal of developing more effective and selective treatments. This method may continue to be useful as our ability to explore the actions of these drugs moves beyond the pharmacology of membrane receptors to intracellular processes (Gould et al. 2004). However, the strategy of understanding a disease through the neurobiology of a prototypical therapeutic drug ultimately reaches an asymptote. Moreover, this approach not only limits the discovery of novel treatments, but also has the broader impact of biasing research on the etiology of the disorder toward mechanisms related to existing drug treatments (Baumeister and Francis 2002). Importantly, this leaves a gap in the understanding of the etiology of the disorder and a significant proportion of patients untreated (Berton and Nestler 2006, Lieberman et al. 2005). A more viable strategy to the study of the neurobiological basis of a psychiatric disorder is to use clinical and epidemiological findings to develop animal models. The purpose of an animal model in psychiatric research is to simplify a problem that is otherwise intractable because of the many factors that need to be investigated to fully understand the disorder. The etiology and symptomatology of disorders such as schizophrenia, depression, and anxiety are complex. However, models of specific components of each of these disorders can be established in experimental animals and can accomplish four aims: (1) elucidate neurobehavioral and neurocognitive processes operating in the disorder, (2) examine candidate mechanisms of pathogenesis, (3) evaluate the plausibility of etiological hypotheses, and (4) identify molecular and neural-circuit targets for novel treatments.

Animal models work best when, as in certain neurological disorders, there is (1) a relatively well-defined syndrome to model as, for example, the cluster of identifiable neuropathological markers in Alzheimer’s disease, or (2) a known etiology, such as the single gene mutations that occur in Huntington’s disease or Rett’s syndrome. In those cases for which causal genes have been discovered, scientists were able to identify a cardinal phenotype, and then select a family or isolated population in which the cardinal phenotype, even if complex, is highly stereotyped. The success of this strategy is exemplified in the discovery of genes for Huntington’s disease and Rett’s syndrome, where the genetic lesions discovered through linkage studies have proven to exist in the affected population as a whole, and have been proven in animal models to produce key aspects of the disorders (Hackam et al. 1999, Zoghbi 2005). However, even these clear-cut successful examples illustrate the complexities in understanding and treating a nervous system disorder, even with good animal models. More than a decade after confirming the disease-causing gene in Huntington’s, the biological pathways leading from the gene to the diagnostic neuropathology, and the links between neuropathology and behavioral symptoms, remain under intense investigation (Landles and Bates 2004). Thus, although innovative animal research has revealed key aspects of the etiologies of neurological disorders such as Huntington’s disease, in the course of recapitulating what was assumed to be the necessary and sufficient neuropathology, researchers have found that the pathogenesis...
of the neurobehavioral syndrome is more complex than anticipated.

Modeling psychiatric disorders is likely to be even more complex, given that there are almost certainly multiple genetic, environmental, and experiential factors that underlie the development of these disorders. At the level of genes, the weight of evidence suggests that schizophrenia, depression, and anxiety are polygenic: each gene confers a small proportion of risk to the population and the set of genes contributing to the disorder may not be the same from patient to patient (Norton et al. 2006). Indeed, the approach that identified the primary causal genes in Huntington’s disease and Rett’s syndrome, linkage analysis, has thus far identified susceptibility genes in schizophrenia. For example, a linkage study of a family in Scotland with a high incidence of psychotic disorders revealed a translocation of a region of human chromosome 1 containing the Disc1 gene. Neurobiological studies of Disc1 provide a high level of plausibility for the involvement of the gene in aspects of schizophrenia and depression (Hennah et al. 2006). However, unlike the huntingtin gene in Huntington’s disease, Disc1 abnormalities are not a common feature across schizophrenia patients (Norton et al. 2006). Thus, in discerning the genetic basis of these psychiatric disorders, we must deal with (1) genetic pleiotropy, the probability that one gene affects more than one trait, and (2) trait complexity: the fact that the traits underlying psychiatric disorders are disruptions of adaptive behaviors that are, in turn, modulated by multiple genes. This reality, combined with the large number of genes expressed in brain cells (55% of the genome) and the probabilities for biologically significant mutations in multiple loci within a gene, leads to the possibility that underlying even the most narrow classification of a mental illness “may lie a vast diversity of potential behavior-impairing mutations across the thousands of genes involved in brain development” (Keller and Miller 2006). Not surprisingly, links between specific genes and psychiatric illnesses are only now beginning to be delineated (Harrison and Weinberger 2005, Norton et al. 2006). Moreover, in contrast to some genes linked to Alzheimer’s disease, the biological effects (e.g., effects on protein structure or function) of psychiatric disease-related genetic polymorphisms are, as yet, unknown (Harrison and Weinberger 2005). At the next level of complexity, susceptibility polymorphisms interact with environmental factors that impact on embryonic and postnatal development (Cannon et al. 2003). Lastly, the limitations or neural “biases” that are set by genetic or early-life factors interact with—and may limit—the experience of the person (i.e., learning), which, in turn, is essential for normal neural and behavioral maturation. In summary, three domains of etiologic factors, “genetic/epigenetic,” “environmentally induced injury” and “experience” interact to determine risk for a psychiatric disorder. Figure 17–1 shows a model by which these factors interact to influence neural function, psychological processes, and behavior. We argue below that the best strategy for understanding how these etiologic factors lead to a psychiatric disease is to study the effects of these factors on neurocognitive and neuroaffective constructs, that is, the relationship between neural function and a cognitive or affective process. Animal models can be used to understand these processes, and that understanding can then be applied to the corresponding human behaviors.

![Figure 17–1](image_url) Three domains of etiologic factors in psychiatric disorders. Genetic/epigenetic factors are familial and pre- or neonatally programmed limits on gene expression. “Environmental exposures” cause permanent biochemical or physical injuries to the brain that may also limit gene expression or neural function. The experiential domain represents an iterative process involving the organism reacting to and acting on the environment. As shown in the “blue pathway,” genetic code and early environmental exposures set limits on developmentally programmed gene expression, environmentally induced gene expression, and neural function. These limitations on neural-circuit function, in turn, limit and/or bias sensory input and/or cognitive or affective processes. The behavioral output from such a system is less adaptive. The “red pathway” shows the influence of experience on cognitive and affective processes. “Events” include stimuli and contingencies that promote or threaten individual survival or procreation. Skewed cognitive processing conferred by factors in the blue pathway may lead to maladaptive behavior and adverse outcomes. As a result, the process by which experience affects neural function and structure is altered. Thus, genetic and early environmental factors form limits that, in turn, alter the cumulative effects of experience on brain and behavior. Traditionally, “etiologic” animal models have been designed to measure the effects of manipulating factors in the blue pathway, whereas “psychopathology” models manipulated factors in the red pathway. Ultimately, however, the animal experiment should model the effect of a specific etiologic factor on (1) a cognitive or affective process known to be disrupted in a psychiatric disorder and (2) the operation of neural circuits hypothesized to mediate the psychological construct.
Defining Phenotypes and Establishing Validity in Animal Models

Defining the Phenotype to be Modeled
Despite, or arguably because of, the complexity in modeling psychiatric disorders, it is essential to approach the goal of defining the phenotype to be modeled and establishing the model’s validity using rational strategies that have been successful for neurological disorders (Lewandowski and Small 2005). The best of these strategies involve three steps: (1) to identify one or a set of cardinal phenotypes of the disease, (2) to operationalize each phenotype, (3) to test the effects of candidate genetic and environmental determinants of the disease on the cardinal phenotype(s). For disorders such as Alzheimer’s disease, which shares behavioral phenotypes (e.g., memory deficits) with other etiologically distinct diseases (e.g., multi-infarct dementia), the most successful approach has been to relate the cardinal behavioral phenotype (e.g., memory deficits) to a neuropathological phenotype (e.g., decreased hippocampal blood volume or presence of plaques or neurofibrillary tangles), and then search for genetic variation associated with the neural phenotype (Lewandowski and Small 2005). The more precise the description of the behavioral and neuropathological phenotypes, the higher the probability is of discovering the underlying genetic basis. Thus, the success of this strategy depends on a robust operational definition of a neuropsychological or “neurocognitive” phenotype. This is a description of a behavioral abnormality that incorporates a knowledge of the neural circuits essential for the operation of the psychological processes underlying the affected behaviors (Chudasama and Robbins 2006, Everitt and Robbins 2005). Table 17–1 shows a number of affective and cognitive processes that are affected in psychiatric disorders such as schizophrenia, anxiety, and depression.

The definition of a “neuroaffective” or “neurocognitive” phenotype affected in a psychiatric disorder depends not only on the precise description of the psychological process involved, but also on an accurate characterization of the neuropathology correlated with the abnormal affective or cognitive function. These neural correlates are determined in vivo with structural and functional imaging (Davidson and Heinrichs 2003, Laruelle 2000) and electrophysiological methods (e.g., electroencephalography) (Braff et al. 2001, Shelley et al. 1999); they are also revealed through postmortem histopathological studies (Harrison 2004, Lewis 2002). In psychiatric disorders, the cardinal behavioral phenotypes are often not exhibited by experimental animals. However, there is now a significant amount known about the neuropathology associated with these disorders (Harrison 2004, Harrison and Gittins 2003, Lewis 2002). Thus, the above strategy can be used to examine biochemical mechanisms that might lead to an observed neuropathology (Harrison and Weinberger 2005, Lewandowski and Small 2005, Lewis 2002) and, in parallel, to determine how the experimentally-induced neuropathology impacts behavior (Chudasama and Robbins 2006, Everitt and Robbins 2005, Gimenez-Llort et al. 2007, Moore et al. 2006).

Although animal models have often been designed to understand symptoms of diseases (e.g., psychosis or anxiety), it may be more fruitful to study the determinants of an endophenotype. An “endophenotype” was defined by Gottesman and Gould (2003) as a heritable trait that underpins a mental disorder and is more closely associated with genetic factors than are the disorder’s symptoms. Examples of candidate endophenotypes in psychiatric disorders might be neural processes that mediate reward learning, expectancies for aversive events, or goal-driven behavior. Such endophenotypes may contribute, respectively, to “surface” symptoms such as reduced motivation, avoidance behaviors, and disorganized speech observed in schizophrenia. However, although endophenotypes are essential for modeling genetic etiologies of disease, experiments aimed at understanding environmental regulation of neural activity and behavior are important for understanding the more “proximal” determinants of a psychiatric disorder or its symptoms. The combined knowledge gained from endophenotype-based models and models of environmental or pharmacological regulation of a phenotype will help us understand the spectrum of mechanisms underlying the manifestation of a psychiatric disorder.

Forms of Validity
There are several forms of validity that can be achieved in an animal model. Although these concepts were most commonly applied in personality theory and standardized testing in humans, they are equally useful in developing effective animal models. Complete descriptions of forms of validity and their significance are provided in Robbins (2004). Here we briefly illustrate the usefulness of three key types of validity. Construct validity is arguably critical in the rational development of animal models of psychiatric disorders. In establishing construct validity, researchers draw on well-developed theories about psychological (e.g., emotional or cognitive) “constructs”—processes that cannot be measured directly. Experiments guided by these theories have produced a wealth of data in humans and experimental animals showing how such constructs affect behaviors. As an example, unlike body temperature, selective attention cannot be measured directly. However, based on a well-accepted operational definition of selective attention, we can infer that this process is modulating a behavior (e.g., identifying a friend’s face) if the behavior is disrupted by adding irrelevant stimuli to the environment. The distinction between the overt behavior and the underlying psychological construct is important for at least two reasons. First, most generally, an overt behavior may be affected by different psychological processes at different times. Following the previous example, one may fail to identify a friend’s face because the memory for the features of the face is inadequate or because one’s ability to filter out the other faces in the crowd, that is, selectively attend to the relevant face, is impaired. The second reason, more directly relevant to animal models, is that while psychological constructs may operate similarly across species, the behaviors that can be quantified may be different. For example, loss of “executive control” over responding might be measured by inappropriate speech in a human, reaching in a nonhuman primate, or nose-poking in a rat. When possible, it is best to try to use similar behaviors (e.g., lever pressing). However, what is essential for psychological and neural construct validity is that the behavioral response of the experimental animal changes as a function of the same environmental and biological factors that
are hypothesized or known to modulate the disease-related behavior in humans.

The predictive validity of the model is assessed by testing how the model responds to the treatments or factors known to improve or exacerbate the relevant symptoms of the disease. Finally, it is important to use complementary experimental methods and different target behaviors to test a hypothesized relationship between a neural phenotype and a psychological construct. Such an approach adds convergent and/or discriminant validity to the model.

**Dissecting Cognitive and Behavioral Endophenotypes from Complex Mental Disorders**

The first step in identifying a neurocognitive phenotype in a psychiatric disorder is considering the psychological process or *construct* that might be most closely related to particular symptoms. A great advance in understanding basic cognitive functions in schizophrenia has been achieved, at least in part, using first monkeys and then rodents to explore the cellular basis of working memory in the prefrontal cortex and to study the parallel impairment in schizophrenia (see Goldman-Rakic 1998). Similarly, in the area of drug abuse, it is hard to reject the evidence that the simple operant paradigm of drug self-administration through intravenously implanted catheters in mice, rats, or monkeys is highly predictive of which drugs are likely to be abused in humans. In theoretical terms, there is considerable evidence that this self-administration behavior taps into a fundamental brain reinforcement mechanism that includes basal forebrain structures such as the ventral striatum (Everitt and Robbins 2005). There is, indeed, a case for considering drug self-administration behavior to be perhaps the most convincing and best validated of all animal models of neuropsychiatric
disorders (Le Moal et al. 2007). At the more controversial end of the spectrum, positive symptoms of schizophrenia such as hallucinations and delusions, or symptoms of depression and anxiety such as ruminations of low self-worth, are often cited as examples of psychopathology which cannot have measurable equivalents in experimental animals. However, these assumptions may be premature, as is illustrated by the following examples of models of neurocognitive and neuroaffective phenotypes in these disorders.

**Modeling Neurocognitive Phenotypes in Schizophrenia: From Sensory Gating to Cognitive Flexibility**

Core cognitive and behavioral phenotypes in schizophrenia have been identified primarily by “reformulating” the interpretation of symptoms to postulate cognitive processes that may underlie the symptoms. For example, delusions and disorganized behavior might both be conceptualized as failures in the “reference” and “working memory” processes necessary to maintain goal-directed behavior. In addition, cognitive phenotypes have been revealed by using quantitative tests that were originally developed to understand normal cognition or test-specific cognitive abilities in nonpatient (often military) populations as predictors of job performance. Examples of these cognitive constructs and the key features of the rodent behavioral tasks that are used to measure them are presented in Table 17–1. A useful and the key features of the rodent behavioral tasks that are predictors of job performance. Examples of these cognitive constructs and the key features of the rodent behavioral tasks that are used to measure them are presented in Table 17–1.

**Sensorimotor Gating and Latent Inhibition**

Sensorimotor gating and latent inhibition are constructs that involve the influence of the automatic encoding of neutral stimuli on subsequent reflexive or learned behaviors. These constructs show a high level of homology across species, and the rodent models for both of them have elucidated the neural circuitry and pharmacology of antipsychotic drug (APD) effects.

Sensorimotor gating is the process by which a reflexive response to a stimulus is blunted by an almost immediately preceding, less salient (indeed, hardly detectable), surrogate stimulus. Prepulse inhibition (PPI) is a useful objective index of sensorimotor gating. PPI follows the same psychophysical principles and is mediated by similar neural circuits across many species, including humans, monkeys, and rodents (Geyer et al. 2001, Swerdlow et al. 2001). These features of PPI, along with the fact that it is reduced in schizophrenia patients, makes it an optimal paradigm for evaluating neuropathology or pharmacology relevant to schizophrenia. The utility of PPI in preclinical schizophrenia research has been extensively reviewed (Geyer et al. 2001, Swerdlow et al. 2001). PPI deficits are neither diagnostic for nor unique to schizophrenia. The main strength of the model has been its construct validity with regard to the neural circuits that are abnormal in schizophrenia and its predictive validity with respect to APDs (Geyer et al. 2001).

The acoustic startle reflex response is mediated by brainstem mechanisms, but PPI itself represents a top-down modulation of this circuitry by hippocampal-striatal circuitry that is homologous to circuits implicated in schizophrenia (Swerdlow et al. 2001). PPI can be disrupted by excessive limbic striatal dopamine transmission, a mechanism that has long been postulated to mediate psychotic symptoms in schizophrenia (Laruelle 2000). Accordingly, APDs that primarily block dopamine D2 (DRD2) receptors (the “typical” phenothiazine and butyrophenone APDs) reverse dopamine-agonist-induced PPI deficits. An important finding in preclinical schizophrenia research was that PPI deficits induced by the nondopaminergic psychotomimetic phencyclidine could be reversed by the atypical APD clozapine but not DRD2 antagonists. Although PPI can be sensitive to drugs that have no antipsychotic efficacy, this paradigm has been valuable in dissecting the pharmacology of “atypical” APDs in pharmaceutical development (Geyer et al. 2001, Hagan et al. 2005). The sensitivity of PPI to neurodevelopmental manipulations that produce schizophrenia-relevant histopathology or pathophysiology in limbic cortical circuits (Geyer et al. 1993, Lipska et al. 1995, Moore et al. 2006) is likely to open new views on the role of PPI in animal models of psychiatric disorders.

Latent inhibition (LI) was discovered by animal learning theorists; it is the process by which preexposure to a neutral stimulus (e.g., a tone or light) retards the formation of a Pavlovian association between the stimulus and an unconditioned (usually aversive) stimulus (US). Theoretically, through covert attention to the stimulus during the preexposure, the animal learns that the stimulus predicts the absence of a significant event. This contingency must then
be extinguished during the learning of the new contingency between the neutral stimulus with the aversive US (Weiner 2003). LI is mediated by limbic cortical and striatal regions, which exhibit pathologies that correlate with the positive symptoms of schizophrenia. Moreover, multiple clinical studies indicate that LI is disrupted during psychotic episodes and is restored during subchronic APD therapy. Like PPI, LI has been useful in predicting or categorizing pharmacotherapies in schizophrenia. However, its most important role in preclinical research may be as a model of the roles of the entorhinal cortex and specific striatal subregions in relatively automatic cognitive processes that, in turn, may disrupt the cognitive “switching” necessary to recognize and adapt to new environmental contingencies (Weiner 2003).

**Modeling Cognitive Flexibility, an Executive Function Disrupted in Schizophrenia**

A test of cognitive flexibility, the ability to shift attention from one aspect of an object to another, used in the assessment of patients with frontal lobe damage is the Wisconsin Card Sort Test (WCST). The WCST and more parametric “response-rule-switching” tasks have been extremely useful challenge tests for schizophrenia patients. The patients show deficits in these tasks, and the recruitment of the frontal lobe by these tasks is abnormal in these patients, as shown by functional brain imaging. Thus, the neuropsychological tests of “executive function” have had a prominent role in the development of the idea of “hypofrontality” in schizophrenia (Weinberger et al. 1988). In the Cambridge Neuropsychological Test Automated Battery, the WCST has been reconfigured to produce a simpler suite of tasks, not only for humans but also for animals, that reflect the building blocks of this complex cognitive test. In short, two perceptual dimensions (e.g., shape and color) are defined and compound stimuli are formed by combining exemplars of the two dimensions. The subject is then trained to discriminate the dimensions on the basis of trial-and-error feedback, and learn which exemplar is correct. This discrimination may be reversed so that the alternative object is correct and the formerly correct stimulus wrong. When the subject has learned to discriminate and reverse this discrimination, new exemplars are introduced with the same dimension remaining relevant. This is called an intradimensional shift and requires the establishment of an attentional set, through “learning-to-learn.” Eventually, having learned to form an overall set in this way, new exemplars are again introduced, and the subject is required to shift attention to the alternative dimension. This is called an “extradimensional shift” and is a core element of the WCST.

The neural basis of this set-shifting behavior has been studied in marmoset monkeys with fiber-sparing lesions of the lateral prefrontal cortex or orbitofrontal cortex. Strikingly, whereas reversal learning was impaired by lesions to the orbitofrontal cortex, extradimensional shifting was deficient following lesions to the lateral prefrontal cortex, thus demonstrating a “double dissociation” of the roles of these two prefrontal cortex regions in these different forms of shifting behavior (Dias et al. 1997). Understanding the basic functions of these two prefrontal cortex regions is a necessary prerequisite for understanding their contribution to cognitive deficits in neuropsychiatric disorders such as schizophrenia and to interpreting the effects of selective neurotransmitter manipulations on these aspects of cognitive performance. This experiment demonstrates the utility of the intradimensional/extradimensional test as a probe of prefrontal cortical function in experimental animals.

Subsequently, the intradimensional/extradimensional paradigm has been validated in studies of humans with frontal lobe lesions (Owen et al. 1991) and using functional magnetic resonance imaging (Hampshire and Owen 2006). This paradigm has now also been generalized to the rat (Birrell and Brown 2000) and to the mouse (Garner et al. 2006) using taste and texture as perceptual dimensions, but embodying the same principles of intradimensional and extradimensional shifting. Thus Birrell and Brown (2000) confirmed Dias et al. (1997) in demonstrating frontal correlates in the rat of different forms of behavioral shifting; this evidence is of theoretical importance in showing a form of functional homology between the primate and rodent brain, even for complex frontal cortex-mediated executive functions relevant to the cognitive deficits in schizophrenia. There has also been considerable work on the neurochemical substrates of this paradigm that are relevant for its use as a model of cognitive dysfunction in psychiatric disorders (Chudasama and Robbins 2006). Because the Cambridge Neuropsychological Test Automated Battery intradimensional/extradimensional test, using the same stimuli as used in monkeys, is sensitive to deficits in patients with schizophrenia (Pantelis et al. 1997), a vertical integration of findings in certain areas appears feasible across species and for human psychiatric disorders.

The positive symptoms such as hallucinations and delusions are regarded as some of the most difficult to model in animals. Although the models of basic cognitive processes such as sensorimotor gating and LI just discussed may be related at some level to psychosis, there is no a priori reason why hallucinations themselves cannot be modeled in animals. Clinicians use not only self-reports by patients to indicate the presence of hallucinations, but also behavioral observations that strongly suggest that a patient is responding to internal stimuli, such as speaking and gesticulating, as if in conversation with an unseen social partner. By analogy, a hallucination might be operationally defined in animals as a complex, voluntary behavioral sequence similar to operant or stimulus-driven behavior, but that occurs in the absence of relevant stimuli or contingencies. Examples include the apparent manipulation of “imaginary” food objects or apparent aversive reaction to a nonexistent object, expressed by monkeys following chronic amphetamine or phencyclidine treatment (Lyon 1991). Similarly paranoid delusions, conceptualized as the attribution of inappropriate salience to stimuli (Kapur 2003), might be modeled in animals.

**Affective Constructs: The Approach–Avoidance Conflict in Anxiety and Depression**

Threat detection, fear-related behaviors, reward processing, incentive, and social drive comprise an interactive cluster of “affective” constructs relevant to all psychiatric disorders (see Table 17–1), but especially anxiety and mood disorders. Animal models of affective constructs are designed by adapting ethological observations to the laboratory, and on quantifying behaviors that appear to be mediated by processes that correspond to human subjective affective states. A key
distinction is between states of fear and anxiety. Any animal, such as a rat or mouse, exposed to highly threatening stimuli, such as a cat, shows characteristic responses (Blanchard et al. 1997). In the immediate presence of the cat, the rat’s defensive options depend on whether it can escape or not. If it can escape, then it will flee (“flight”), or if there is no route of escape, it may exhibit immobility, or “freezing” behavior, which deprives the predator of sensory cues needed to locate it. As a last resort, the rat may exhibit defensive aggression. Besides biting, the rat may vocalize, which serves a social function, that is, signaling the presence of danger to other rats. (It should be noted that vocalizations and other specific behaviors distinguish defensive aggressiveness from predatory behavior.) Collectively, all of these behavioral responses to the predator’s immediate presence can be defined as fear. By contrast, “anxiety” might be defined as a process involving (1) the detection of unconditioned (e.g., odor) or learned cues that predict danger and (2) the physiological and behavioral responses to these cues, by which the animal can avoid the danger.

Another concept of anxiety involves conflict. In general, an animal’s environment contains a mixture of oppositely valenced cues: appetitive (e.g., predictive of food, water, safety, or sex), neutral, and aversive (predictive of life-threatening or painful events) ones. The cognitive processing of and behavioral responses to these cues are governed by the animal’s internal state (e.g., hunger) and the cues’ salience or predictive power. Thus, in the wild, animals are continually in conflict between approach and avoidance tendencies. Since Freud, the conflict between desire and fear has been central to our concept of anxiety. The resolution of the conflict is highly influenced by the appraisal of stimulus-outcome contingencies. Many studies have now shown that a “threat-detecting” bias revealed in cognitive tasks predicts trait anxiety and/or diagnosis of an anxiety disorder (Chan et al. 1996). Moreover, continued avoidance behaviors limit the organism’s engagement in incentive learning and positively reinforced behaviors, a diagnostic feature of depression.

Additional construct and etiologic validity for conflict tests can be found in environmental or developmental models of heightened anxiety. Specifically, peripubertal social isolation, a manipulation shown to be associated with anxiety in humans, produces anxiety-like profiles on conflict tests, as well as pathology in the cortico-limbic regulation of stress hormones in rodents (Serra et al. 2000). Other cross-species examples can be found in the inhibition of appetitive behaviors, including play or solicitation of the mother, in juvenile humans, monkeys or rats when confronted by a potentially threatening social stimulus (Hofer 1996, Kalin and Shelton 1998). A high tendency toward avoidance (“shyness”) can be a juvenile behavioral trait marker for anxiety later in life (Muris 2006).

There are well-validated behavioral paradigms used to model conflict in rodents (Broekkamp and Jenck 1989). In some of these, the stimulus is designed to evoke both unconditioned appetitive and avoidance behaviors. Such models include (1) the light–dark shuttle box, in which the rodent’s tendency to avoid open (e.g., well-lit) areas conflicts with a learned aversive association (foot shock) with the dark chamber; and novelty-suppressed feeding, in which the tendency to approach and consume a food bait is in conflict with the bait’s location in the brightly lit center of a novel open field. In other tests, positively reinforced responses are suppressed by contingent punishment. These tests include the punished drinking test, in which licking from waterspout is punished by electric shocks, and the safety signal withdrawal operant paradigm, in which suppression of lever pressing for food is induced by the withdrawal of a conditioned signal for safety. Behaviors in other tests, such as locomotion in a novel open field, can certainly be modulated by conflict. However, the most interpretable tests are those in which the two conflicting “drives” are systematically manipulated. In the next section, we review basic studies on the pharmacology and neural circuitry underlying conflict behavior and fear and show that these models have provided strong validation of the primacy of this construct in anxiety.

Using Neuropathological or Pharmacological Phenotypes to Test Etiologic and Pathogenic Hypotheses of Psychopathology

Ideally new animal models should drive translational research, which involves two strategies that are employed in parallel: (1) sorting human samples according to behavioral traits relevant to psychiatric disorders in order to investigate hypothesized neural systems or genetic differences that account for the behavioral effect, and conversely (2) disrupting candidate genes, neurotransmitter systems, or neural circuits in animals to determine their role in the animal’s behavior that models the psychological processes impaired in a psychiatric disorder. For example, a study finding a correlation between a neural phenotype and a behavioral abnormality in humans would generate the hypothesis that the neural system is necessary for, or mediates, a specific psychological construct (i.e., function). That hypothesis would then be tested using animal models in which the neural system is directly manipulated (e.g., by lesions or pharmacological or genetic manipulation), and the effect on behaviors related to the psychological construct of interest is measured. Throughout this process, convergent and construct validity are important. If a number of complementary methods are used to manipulate the target neural system, and the results converge on a set of behavioral outcomes that are consistent with the theorized operation of the psychological construct, then convergent and construct validity have been established. This increases the probability that the neural target is important for the psychological process underlying the human symptom. In the next section, we provide examples from basic and translational research in anxiety and schizophrenia to illustrate this point.

The Anatomy and Pharmacology of Conflict Behavior: An Example of “Full Reciprocal Translation” in Anxiety Research

Animal models of the neural substrates of fear and conflict behavior have been central to the search for pathogenic neural processes and molecules for anxiety disorders. The neural circuits necessary for anxiety-related (i.e., high avoidance) or fear behaviors in rodents center on the amygdala (Davis et al. 2001, LeDoux 1992) and correspond to the brain regions implicated in anxiety by functional neuroimaging studies (Strange et al. 2006). Consistent with the importance of the constructs of threat detection and avoidance in anxiety, predator threat in rodents leads to changes in...
neurotransmission in the amygdala (Roseboom et al. 2007). Alterations in forebrain serotonin transmission also mediate fear and anxiety. For example, serotonin (5HT) reuptake inhibitors or agonists selective for the 5HT1A receptor modulate conflict behavior and are therapeutic as treatments for anxiety (Broekkamp and Jenck 1989). Genetic or developmental pharmacological manipulations of serotonin transmission in mice produce specific abnormalities in conflict behaviors, which suggests that these molecules modulate the bias toward avoidance or defense during the appraisal of ambiguous or mildly aversive situations (Ansorge et al. 2007, Gross and Hen 2004, Weisstaub et al. 2006). The data from gene expression mapping across specific brain regions and the effects of tissue-specific manipulations of gene expression on conflict behaviors have led to more specific hypotheses regarding serotonin transporter or receptor modulation of specific limbic and cortical circuits in anxiety (Plath et al. 2006, Weisstaub et al. 2006). One example of “fully reciprocal translation” in modeling the neurobiology of anxiety has been identification of genotypes that lead to more or less activity at the serotonin transporter. The genetic mouse models predicted that in humans the genotypes would have functional significance for cortico-limbic activity and the processing of the “aversiveness” of stimuli in the environment. This prediction was borne out by studies combining genotyping, functional imaging, and anxiety trait assessment in normal humans (Hariri and Holmes 2006).

Models of Neuropathological and Pathophysiological Phenotypes in Schizophrenia

Animal behaviors that may bear little resemblance to the human behavior being modeled can nevertheless have construct validity in modeling the neural pathology of behavioral symptoms. Schizophrenia, used as an exemplar in this section, is diagnosed by positive (hallucinations and delusions) and negative (anhedonia, social withdrawal, alogia) symptoms, but also characterized by cognitive deficits (see Table 17–1). There is now a considerable literature on the correlations between symptom domains and neuropathology. Neurobehavioral hypotheses of schizophrenia under active investigation include (1) dopamine “imbalance” consisting of excessive or dysregulated striatal dopamine (DA) transmission (Kapur 2003, Laruelle 2000) coupled with deficient frontal cortical DA transmission (Abi-Dargham et al. 2003, Goldman-Rakic 1998) and (2) specific disruptions of glutamate- or GABA-mediated neurotransmission in cerebral cortex. These pathogenic processes are likely to be related. Indeed, animal models have shown that the pattern of spike activity of neurons projecting from the prefrontal cortex and hippocampus is determined by glutamateergic synaptic input from thalamic and other cortical regions and is tightly controlled by GABAergic interneurons (Gonzalez-Burgos et al. 2005, Klausberger et al. 2003). This cortical activity, in turn, regulates subcortical and cortical dopamine systems (Floresco et al. 2001, 2003) (Figure 17–2). In schizophrenia, activity in prefrontal cortex (PFC) and anterior medial temporal cortex (hippocampus and parahippocampal cortex: HIPP) are dysregulated by abnormal dopaminergic and GABAergic inputs onto the cortical projection neurons, and by alterations of synaptic structure and signal processing intrinsic to the projection neurons. This produces abnormal signaling from the PFC and HIPP to other cortical regions and to the striatum (STR). As described in Section “Modeling Neurocognitive Phenotypes in Schizophrenia,” frontal and limbic (e.g., hippocampal and parahippocampal) cortico-striatal circuits, and their modulation by dopamine, mediate a number of important cognitive processes affected in schizophrenia and have been hypothesized to underlie the positive and negative symptoms of schizophrenia (Moore et al. 1999).

At the level of symptoms, psychotic symptoms have been found to correlate with excess metabolic activity in the HIPP (Harrison 2004, Schobel et al., in press) and increased DA transmission in STR (Laruelle 2000), whereas negative symptoms and cognitive deficits are associated with decreased metabolic activity in the PFC, decreased anterior temporal lobe size, and presumed decreases in cortical dopamine transmission (Abi-Dargham et al. 2003, Goldman-Rakic 1998, Sigmundsson et al. 2001). There is also substantial support for the hypothesis that these neural phenotypes arise from genetic and environmental factors.
influencing brain development (Harrison and Weinberger 2005). Below we review examples of models in which the relationships between disease-relevant neuropathology and key cognitive or affective constructs in the disorder are characterized.

The Cortical–Subcortical Dopamine Imbalance in Schizophrenia

Any model of schizophrenia has to take account of the fact that dopamine D2 receptor blockade is an effective treatment for the positive symptoms (Laruelle 2000). The dopaminergic neurons of the mesencephalon project to the frontal cortex, the hippocampus, and many subcortical regions (Gardner et al. 2000) (Figure 17–2). The most densely DA-innervated structure in the forebrain is the striatum. Several lines of evidence suggest that enhanced DA transmission in the striatum is an essential mechanism of psychosis. First, the efficacies of most APDs correlate with their affinity for D2-like receptors (Seeman and Seeman 1987). Second, abuse of DA-releasing drugs, especially amphetamine, can lead to schizophrenia-like paranoid delusions (Laruelle 2000). Most of these actions appear to depend on regulation of the mesolimbic dopaminergic system by limbic afferents from structures such as the basolateral amygdala and hippocampus (Moore et al. 1999). As described above and shown in Figure 17–2, excess limbic drive of subcortical DA may mediate psychosis. Thus data from animal models converge with human data to support the hypothesis that cortical or limbic “dysregulation” of striatal DA transmission may disrupt the evaluation of the significance of stimuli, and that this neurobehavioral pathology may contribute to hallucinations.

Reduced DAergic innervation of the frontal and temporal cortex has been observed in postmortem studies of schizophrenia. This may be one neuropathological underpinning of reduced functionality of the frontal cortex in this disorder (see Section “Modeling Neurocognitive Phenotypes in Schizophrenia”). The dopamine D1 receptor has long been associated with cognitive function such as working memory within the PFC, with both diminished and excessive D1 receptor stimulation disrupting functions such as working memory (Abi-Dargham et al. 2003, Goldman-Rakic 1998). This is consistent with a large amount of evidence in experimental animals that working memory and attentional functions depend upon the integrity of the prefrontal cortical DA system (Crofts et al. 2001, Goldman-Rakic 1998). The hypothesis is relevant to the parallel working memory deficits shown by monkeys with mesocortical dysfunction, and schizophrenics tested in delayed saccade and other procedures suitable for measuring working memory (Goldman-Rakic 1998, Park and Holzman 1992). It may also account for the deficits found in abstracting rules in the Cambridge Neuropsychological Test Automated Battery extradimensional/extradimensional task (Pantelis et al. 1997). Similar deficits in this task have been found in monkeys with mesocortical DA loss (Crofts et al. 2001). Consistent with these studies are studies in monkeys in which a down-regulation of cortical D1 receptors produced by chronic D2 antagonist administration (Castner et al. 2004) also impairs working memory. The apparent paradox of having increased subcortical DA function coupled with reduced cortical DA activity in schizophrenia has been modeled in experimental animals showing that selective lesions of the frontal cortical DA system increases the responsiveness of the striatal DA system (Boyce and Finlay 2005, Venator et al. 1999). An inverse relationship between prefrontal cortical activity and striatal DA function has also been shown in human imaging studies. Specifically, in schizophrenic patients performing the WCST during scanning, the task-related increase in blood flow in frontal cortex in frontal blood flow was reduced and this deficiency correlated with DOPA uptake, a presynaptic marker for DA, in the striatum (Meyer-Lindenberg et al. 2002). Combined, these studies predict that administration of drugs that selectively boost cortical DA D1 receptor function would improve cognitive functioning in schizophrenia.

An example of a bottom-up approach that tests the converse of the “cortical regulation of striatal dopamine” is a genetic model recently reported by Kellendonk et al. (2006). The tissue-specific mutation of the DA D2 receptor gene produces a reversible overexpression (by 15%) of striatal dopamine D2 receptors. This model approximates the excess D2 receptor binding observed in schizophrenic patients (Laruelle 2000). Overexpression of postsynaptic D2 receptors in the striatum throughout development leads to deficits in cognitive functions normally mediated in part by the PFC, and increased D1 receptor transduction in the PFC. Importantly, turning off the transgene in adulthood can normalize D2 receptor number, but reverses the D1 receptor abnormality in the cortex, resulting in abnormally low receptor functionality there. This finding is consistent with a neurodevelopmental role of D2 receptors in the pathogenesis of schizophrenia-relevant phenotypes, and with the data indicating that an optimal level of D1 receptor functionality in the frontal cortex is necessary for normal working memory. Similar to the “full reciprocity” described for the genetic models of anxiety described above, this mouse model has been used to predict a relationship between cognitive function and a functionally significant variant in the DA D2 receptor gene. Neuropsychological testing has provided evidence that this overactivity of the receptor is associated with cognitive deficits that are consistent with the cognitive impairments shown by the mouse model (Xu et al. 2007).

Models of Abnormalities in Glutamatergic and GABAergic Synaptic Transmission in Cortical Circuits

The glutamate and GABA hypotheses overlap considerably with the mesocortical DA hypotheses in schizophrenia, deriving in part from evidence of malfunction of glutamatergic and GABAergic (Lewis and Moghaddam 2006) systems in cortical regions important in the regulation of dopamine systems (Moore et al. 1999). The glutamate hypothesis is more precisely a hypothesis of NMDA receptor hypofunction. Evidence from both human and animal models has advanced this hypothesis. Abuse or experimental administration of the NMDA antagonist phencyclidine (PCP) or ketamine can produce a phenocopy of schizophrenic psychosis, including disorganization, depersonalization, and auditory hallucinations. The effects of PCP abuse can also mimic negative symptoms such as social withdrawal (Jentsch and Roth 1999). Schizophrenia patients are more sensitive than normal
subjects to the psychotogenic properties of phencyclidine. In humans ketamine also produces impaired prefrontal cortical function as evident in impaired “error prediction” signals measured by means of a frontal hemodynamic response in human volunteers. Moreover, these abnormalities in error signal predicted the degree of delusional phenomena experienced by normal volunteers experiencing higher doses of ketamine and the delusional scores on psychiatric scales in patients with schizophrenia (Corlett et al. 2006). These data illustrate how a concept arising from work on associative learning theory in animals and their instantiation of a pharmacological model of psychosis can lead to powerful new models and hypotheses about schizophrenia. Experimental animal models have shown that NMDA channel blockers (PCP, ketamine or MK-801) can, when given acutely or in a sensitization regimen, produce striatal DA hyperactivity (Balla et al. 2001). On the other hand, chronic PCP or MK-801 leads to decreased DA turnover in the PFC and is associated with deficits in tests of working memory or response inhibition (Jentsch and Roth 1999). More recently, the discovery of a number of susceptibility biological pathways has pointed to a primary defect at the glutamatergic synapse on the cortical pyramidal neuron (Harrison and Weinberger 2005). Thus it is likely that NMDA antagonists mimic a loss of calcium-mediated signaling at the glutamatergic synapse onto the cortical pyramidal neuron. This pathology is compounded by loss of normal regulation of the activity of these neurons by specific populations of GABAergic interneurons (Lewis and Moghaddam 2006).

Modeling Neurodevelopmental Pathogenic Pathways

The convergent lines of evidence supporting the notion that schizophrenia is a neurodevelopmental disorder have been extensively reviewed; a recent literature search shows more than 200 review articles on this topic, a few of which are cited here (Cannon et al. 2003, Lewis et al. 2004, McGrath et al. 2003, Singh et al. 2004, Weinberger and Lipska 1995). This evidence has led to animal models of a schizophrenia-relevant form of abnormal brain development. These models are sometimes considered etiologic; however, they do not all start by mimicking known etiologic factors. Rather, a subset of these models aim to mimic abnormal development of key cortico-stratal circuits as pathogenic processes upon which etiologic factors are likely to converge. Unlike distal etiologic factors, these processes are postulated to be more deterministic of proximal risk for symptomatology.

The hallmark studies in this field used focal lesions of the neonatal hippocampus and of adjacent structures known to be affected in schizophrenia (Lipska et al. 2003). Neonatal lesions of the ventral hippocampus lead to an increased behavioral responsiveness to dopamine agonists and stressors that evoke dopamine release in the striatum and limbic regions. These abnormalities emerge during or after puberty, similar to the age of emergence of psychosis in most schizophrenia patients. Neonatal lesioned rats also exhibit abnormal responses to glutamate receptor antagonists such as PCP and deficits in both working memory as well as in PPI, as might be expected in a model of schizophrenia. The implications are that abnormalities in the cortico-limbic systems projecting to the striatum lead secondarily to dysregulation of the ascending dopaminergic systems, perhaps involving a form of sensitization (Lipska et al. 2003).

Another example of “abnormal neurodevelopment models” includes gestational exposure to the nucleic acid methylator methylazoxymethanol acetate (MAM) (Flagstad et al. 2004, Moore et al. 2006, Talamini et al. 1999). Offspring of dams injected with MAM during gestation show structural changes in the hippocampus, perirhinal and entorhinal cortex, the most structurally affected cortical regions in schizophrenia (Moore et al. 2006, Talamini et al. 1999). More specifically, offspring of dams administered MAM at embryonic day (E) 17 exhibit a pattern of gross brain morphology and neurohistopathology that appears similar to what has been reported in schizophrenia. This pattern involves small-to-moderate reductions in cross-sectional thickness, with a disproportionate reduction in the hippocampus, increased neuronal density in the cerebral cortex, and reduced anterior thalamic size (Moore et al. 2006). Importantly, in addition to showing this neuropathological phenotype, MAM E17 offspring also show a postpubertal emergence of supersensitivity to DA-releasing drugs, several cognitive deficits relevant to schizophrenia (Moore et al. 2006), and show increased amphetamine-induced striatal dopamine efflux in adulthood (Flagstad et al. 2004). This shows that validation across neuropathological and neurocognitive phenotypes provide opportunity to examine potential neurophysiological and neurochemical mechanisms that may represent novel targets for pharmacogenomic treatment strategies.

To summarize, animal models have been used to test the plausibility of a number of neurobiological hypotheses regarding the pathogenesis of schizophrenia. Table 17–1 supplements this section by summarizing other important neuropathological phenotypes in schizophrenia that can be measured in experimental animals. Because the validity of experimental models is increased by the homology of the neurobehavioral relationships in the different species, it is becoming paramount to both “neurocognitive” (see Section “Dissecting Cognitive and Behavioral Endophenotypes from Complex Mental Disorders”) and “etiologic” (see Section “‘A Priori’ Modeling Genetic, Environmental and Experiential Etiologies in Psychiatric Disorders”) models of schizophrenia that assessments of neuropathology be included.

“A Priori” Modeling Genetic, Environmental and Experiential Etiologies in Psychiatric Disorders

Just as cognitive and behavioral phenotypes in animals can be used to model the manifestations of psychiatric disease, manipulations of genetic or environmental factors can be used to identify possible etiologic pathways to the neuro- and psychopathologies relevant to psychiatric disorders. These manipulations model the three types of etiologic pathways defined in the introduction: genetic, environmental, and experiential.

Exploring the Functional Significance of “Susceptibility Genes”

Susceptibility genes are identified through association or linkage studies. These studies identify genetic variants or rare mutations associated with increased risk for schizophrenia. A number of susceptibility genes have been identified in schizophrenia (Harrison and Weinberger 2005), anxiety (Hariri
and Holmes 2006), unipolar depression (Urani et al. 2005), and bipolar disorder (Carter 2007). The rodent models of these susceptibility genes usually serve at least one of two aims. The first is to elucidate biological processes regulated by the gene product that might overlap with hypothesized pathophysiology of the disorder. The second, more ambitious aim is to model the genetic variation that has been shown through linkage or association studies to increase the risk for the disorder. A thorough review of how current genetic mouse models are used with respect to these aims can be found in the reviews cited above. Particularly important for establishing etiologic and construct validity in these models is the nature of the genetic variants associated with a given disorder and whether the specific polymorphism or mutation can be reproduced in the genetic mouse model. For example, how does one model a gene allele that does not show sufficient penetrance to be expressed in a large number of cells, but if coincident with other gene variants or epigenetic factors, may contribute to risk? Such possible epistasis of effects has hardly been investigated thus far in rodent models. A final crucial factor to consider is the interaction of the genotype with possible environmental situations or triggers, which may help determine its expression.

The case for most susceptibility genes in psychiatric disorders, particularly schizophrenia, is that the effect, if any, of the risk alleles on the structure or quantity of protein is poorly understood. Moreover, a particular variant may not affect the gene in which it is embedded, but rather, may affect expression of a nearby or even relatively distal gene. In these cases, it is unlikely that a gene “knockout” will serve as an accurate model of the risk allele. Moreover, functional significance of a risk allele must be assessed as a function of brain development. Lastly, as with any manipulation made early in development, genetic mutations will have pleiotropic effects, that is, effects unrelated to the disorder of interest. Given this pleiotropy, it is necessary to control for several confounding factors in genetic models. These include the genetic background onto which a mutation is backcrossed, which will also affect behavior, and the “environment,” that is, the laboratory procedures used to produce and test a genetic model. The emphasis hitherto on using the male gender for most analyses also has to be redressed, given the accumulating evidence for gender-specific genetic effects in psychiatric disorders. Despite the challenges, strategies for measuring neurocognitive constructs are being employed in an increasing number of genetic mouse models with possible relevance to schizophrenia (see Arguello and Gogos [2006] for a detailed review) and other psychiatric disorders (Hariri and Holmes 2006). Continued development of these models will reveal links between susceptibility genes and the neuro- and psychopathology of psychiatric disorders.

**Modeling Environmental Exposures as Risk Factors in Schizophrenia**

Early exposures to environmental toxins or trauma have been shown to significantly increase the risk for cognitive and psychotic disorders. Particularly relevant to the etiology of schizophrenia are rodent models of maternal or paternal exposures or age. For example, nutritional deprivation of the dam during gestation, mimicking starvation or selective deprivation of nutrients such as protein or vitamin D, leads to persistent abnormalities in expression of developmentally regulated genes in the hippocampus, hippocampal neuron morphology, dysregulation of catecholamine systems, as well as PPI and social behavioral deficits in the offspring (Almeras et al. 2007, Debassio et al. 1994, Marichich et al. 1979, Palmer et al. 2004, Rehn et al. 2004). Similarly, the increased risk for schizophrenia in the offspring of women exposed to infection during pregnancy has led to rat models of the prenatal infection or immune activation (Zuckerman and Weiner 2003, 2005). Several studies show that viral infection and immune system manipulations during gestation result in cytochemical abnormalities in the cerebral cortex, as well as deficits in LI and responses to psychostimulants in the adult offspring (Shi et al. 2003, Zuckerman and Weiner 2003, 2005). Advanced paternal age as a risk factor for schizophrenia is a highly replicated finding (Malaspina 2001). While animal models of potential mechanisms of this effect, including de novo mutations and DNA methylation in germ cells, are well developed (Oakes et al. 2003, Walter et al. 2004), there are as yet few studies on schizophrenia-relevant behavioral phenotypes in the offspring (Auroux 1983). Parental exposures to toxins such as lead also increase the risk for schizophrenia in the offspring (Opier and Susser 2005). Teratologic models of these factors exist, but in general, do not adequately model neurocognitive or neuroaffective constructs.

**Experiential Factors in Etiologies of Psychiatric Disorders: Stress and “Maladaptive” Contingency Learning in Anxiety and Depression**

Experiential contributions to psychopathology often invoke the construct of stress, defined by Selye (1956) as a challenge to homeostasis. This concept is often invoked in hypotheses regarding the cumulative effects of “life events,” in the etiologies of mood disorders, and to a more limited extent, schizophrenia. Exposure to stress in experimental animals often entails experiences produced by a regimen of shock presentations, or the imposition of restraint or cold temperatures. However, much more subtle and realistic forms of stress have been employed to reflect the human situation. Social stressors have been much studied in nonhuman primates, but now are increasingly studied in rodent models; for example, early separation from the mother or peers, or both (Champagne and Meaney 2001, Dalley et al. 2002, Mineka and Suiomi 1978). Interest has also focused on situations where there is an important emphasis on the schedule of the stressors and whether they are controllable by the animal, which affects the animal’s ability to marshal coping responses to mitigate the stress (Willner 1997).

**Early Experiences as Etiologic Factors in Adult Psychopathology**

Models of early developmental experiences that contribute to the risk of adult psychopathology include maternal isolation in neonates or social isolation in weanlings. Prolonged or repeated isolation of rat pups from their mothers during the early postnatal period produces persistent and profound behavioral, neurochemical, and epigenetic effects (Champagne and Meaney 2001, Ellenbroek and Cools 2000, Holmes et al. 2005, Meaney et al. 2002). These include epigenetically programmed maternal and defensive behaviors, sensorimotor gating and cognitive deficits, enhanced
Learned Helplessness as an Experiential Etiology in Depression

Learned helplessness is a form of learning that leads to coping behavior that, outside of the learning situation, is not adaptive. This paradigm exposes an animal to uncontrollable, unpredictable aversive events, which leads to a failure to learn avoidance or an escape response to that event even when it is avoidable or escapable (Seligman 1972). This failure to respond is interpreted as a state of helplessness, analogous to the sense of helplessness that is a core symptom of clinical depression (LoLordo 2001). Other phenotypes associated with learned helplessness, some of which are consistent with its status as a model of depression, include elevations in reinforcement threshold, impairments in appetitive behavior and body weight, and sleep disturbance. “Helplessness” can be counteracted by antidepressant treatments such as tricyclic drugs, MAO inhibitors, and electroconvulsive shock regimens, which strengthens its validity as a model of depression. Such antidepressant drugs are often screened using tests that include inescapable stress for mice and a forced swim test (“behavioral despair”) for rats (Porsolt 2000).

Conclusions

This chapter has illustrated the utility of animal models of psychiatric disorders in several ways. The examples, primarily models of schizophrenia, depression, and anxiety, illustrate strategies used to relate cognitive and affective processes affected in these diseases to relevant neuropathology. Animal models will be necessary to delineate disease-specific abnormalities in these systems. Importantly, animal models have heuristic value for developing new hypotheses about the nature and causation of mental disorders. Future modeling attempts should also advance the analysis of the clinical syndromes themselves, from the nosological, epidemiological and therapeutic, to the neurocognitive, pathophysiological and genetic/molecular domains. Ultimately, animal models will advance the understanding of how the multiple etiological factors for mental disorders lead to cognitive and affective phenotypes and their underlying neuronal pathology.

The Scientific Basis of Psychotherapy

The insights that have come from neuroscience research during the past quarter century have begun to provide the opportunities for better understanding the relations of brain and mind. The demonstrated effectiveness of some manu-

Principles of Psychoanalysis: The
Contribution of Freud

In this section, the fraught early attempt of psychoanalysis to place psychotherapy on a scientific footing is reviewed critically to illustrate the difficulties all psychotherapies grapple with in this endeavor. In subsequent sections, recent but still very preliminary, efforts to investigate the neuroscience of psychotherapy are described. The methods of contemporary psychotherapy began at the end of the 19th century with the discoveries of Breuer and Freud (1955). Breuer and Freud, working with Anna O., a patient who suffered from multiple disabling ‘hysterical,’ now called conversion symptoms, which are motor or sensory symptoms that have no neuroanatomic or physiologic cause. Breuer discovered that the recovery of ‘forgotten’ traumatic memories could be achieved by the simple but innovative technique of permitting his patient to talk at random, or free associate. The recovery of these memories led to symptomatic relief.

After a 15-year career as a researcher in neuroanatomy, Freud became a clinician out of financial need. Following Breuer’s lead, Freud treated a number of patients and set out to understand the origins and complexity of the mental operations that he was observing.

Among Freud’s most fundamental insights was that free association led to the origin of patients’ fantasies and memories. Although the distinctions are not always clear, it is useful to differentiate the phenomena that Freud observed in the treatment situation from the explanatory hypotheses that he developed in his attempt to establish a theory of mind. Freud listened to adult patients’ fantasies and memories, and their free associations to these fantasies and memories. From these, he inferred their origin in infancy or early childhood. He then constructed hypotheses to explain
these observations and their putative developmental origins. Among these hypotheses, “Freud Introductory Lectures” (Freud 1963) were:

1. that infantile aggressive and sexual needs, desires, and attachments, and corresponding prohibitions holding these needs and relationships in check, proceed through development into childhood and adulthood.

2. that unresolved conflicts between these early needs and prohibitions, as well as early traumas, although not available to conscious recall, motivate adult behavior and cause symptom formation in mental illnesses. This process of motivation by unconscious mental content is called the ‘dynamic unconscious’ (“Three Essays on Sexuality,” Freud 1953). Anxiety is the affect that signals the presence of an unresolved unconscious conflict.

3. that patients in psychotherapy reenact their earliest relationships in their relationship with the therapist—called the transference. Freud discovered that the transference and its interpretation by the analyst played a central role in the therapeutic process.

4. that the mental mechanism of repression operates to prevent conscious awareness of early conflicts over prohibited desires.

5. that the resolution of conflicts arising from the Oedipus complex, the child’s triangulation of relations between its mother and father and himself (and a parallel complex in girls), plays a central role in directing development towards healthy or maladaptive outcomes.

6. that the patient’s free association to memories, fantasies, and dreams, told to the therapist as they occurred, and the therapist’s interpretation of these, was the most effective therapeutic method to bring repressed unconscious conflicts into consciousness, resolve them, and thereby relieve mental symptoms.

These observations and hypotheses were the foundation of a revolutionary new understanding of mental life and human behavior. Following the logic of basic research, Freud developed a mechanistic and reductionist “metapsychology,” to provide a conceptual framework for the observations and hypotheses that he had formulated in the consulting room. These include the familiar concepts of libido, the source of mental energy and drives; the structural theory of the mind, which postulated the existence of the id, ego, and superego, which contain the unconscious drives and prohibitions; and the pleasure principle, a homeostatic mechanism that underlies all mental activity and aims at maximizing pleasure and minimizing displeasure by reducing libidinal tension. Freud called both the new therapy and its metapsychological conceptualization psychoanalysis.

It was Freud’s early hope that the structures and mechanisms that he postulated could be grounded in the anatomy and physiology of the brain. Stimulated by his own basic research on the nervous system, he attempted to construct a neuroscience-based description of psychic function—the “Project for a Scientific Psychology” (Freud 1966). However, he abandoned this project when he realized that the neurobiology of his time was inadequate for the complexity of mental function that he had described. Freud would have preferred a unitary mind–brain model, but the continued separation of mind and brain was a necessary strategy without better methods for investigating the brain. Freud (1912) said:

Psychoanalysis has talked a lot about the accidental factors in etiology and little about the constitutional one; but that is only because it was able to contribute something fresh to the former, while, to begin with, it knew no more than was commonly known about the latter. We refuse to posit any contrast in principle between the two sets of etiological factors; on the contrary, we assume that the two sets regularly act jointly in bringing about the observed result. Endowment and Chance determine a man’s fate—rarely or never one of these powers alone.

Psychoanalysis after Freud
As the history of psychoanalytic theory and therapy unfolded, metapsychology, which Freud at one point referred to as “the witch” (Freud 1937) because it reified theoretical constructs without any basis in biology, became a larger part of psychoanalytic theory. The seemingly insurmountable gap between metapsychology and biology led to an attitude and conviction on the part of psychoanalysts that psychoanalysis was a self-sufficient realm of exploration, and efforts to introduce reductionist materialist concepts were generally rejected out of hand. Developments in neurobiology were either ignored, viewed as irrelevant, or actively rejected as representing sources of reductionist interference with the ongoing effort to understand mental function.

With neuroscience still in its infancy, psychoanalytic hubris went unchecked. With little objective evidence psychoanalysts claimed therapeutic success treating ulcerative colitis, peptic ulcer, rheumatoid arthritis, bipolar disorder, the varieties of depressive disorder, schizophrenia, and other disorders. The placebo effect, although well known, was ignored, and outcome studies, considered desirable, were generally dismissed as too difficult to undertake, ignored, or even regarded as irrelevant to psychoanalytic pursuits.

The confluence of three research areas radically altered this situation: (1) clinical psychopharmacology, (2) behavioral observation of infants and young children, and (3) basic neurobiologic animal models of memory and affect.

1. The discovery of chemical transmission in the brain in the 1940s and 1950s, accompanied and/or drugs that affect specific forms of chemical transmission mandated reassessment of the putative role of psychodynamic mechanisms in psychopathology and the nature of therapeutic action of psychoanalysis. Depressive mood, excessive anxiety, panic attacks, tics, so-called psychosomatic disorders, manic states, psychotic delusions and hallucinations, unstable forms of attachment all respond to medication to varying degrees. Although for each of these conditions psychodynamic mechanisms have been hypothesized, the relevance of such formulations varies from case to case. For some patients, a psychotherapeutic approach may provide them with insight and have some effectiveness, for others psychotropic medication is the treatment of...
choice. Current research indicates that for some patients, a combination of medication and psychotherapy is still more effective. The psychodynamic community initially responded with hostility to the use of medications for anxiety and depression, claiming that removing symptoms prior to altering the underlying psychodynamic etiology would be counterproductive, leaving the patient with unresolved conflicts that would continue to interfere with the pursuit of life goals. Clinical evidence quickly demonstrated that, to the contrary, symptom removal alone was highly beneficial. Without crippling symptoms of anxiety or depression, patients were often able to reorganize their intrapsychic functioning in healthy ways without much further assistance. Their enhanced self-esteem and renewed self-confidence permitted bolder and more creative responses to the outer world. The overwhelming evidence for the benefits of symptom removal per se eventually persuaded the psychodynamic community that patients freed of overwhelming affective states were better able to explore their unconscious conflicts. Survey data today indicate that a large proportion of patients in psychoanalysis are also receiving some variety of psychotropic medication.

2. Beginning in the 1950s, John Bowlby, a psychoanalytically trained psychiatrist, set out an ethologically based theory of the attachment relationship between an infant and its mother, which complemented, and in many ways challenged, the psychoanalytic libido and structural theories. Attachment theory placed the infant’s relationship with its mother on an equal footing with satisfaction of its basic physiological needs as a primary influence on development. At around the same time, Rene Spitz documented the profound deleterious effects on infant development of major disruptions in the attachment relationship that occurred in institutionalized infants, while Harry Harlow used an animal model (the rhesus monkey) to show how maternal separation experienced in infancy causes major lifelong impairments in psychological and social function. In the 1960s and 1970s, several investigators and theorists extended these findings. Mary Ainsworth tested Bowlby’s theory in the laboratory with human infants and their mothers, and developed a standard observational evaluation of the quality of the infant’s attachment relationship. This method has given rise to prospective studies of the effects of normal and disturbed attachments on a number of developmental outcomes and to correlational studies of infant attachment quality with maternal psychopathology. At about the same time, the psychoanalysts Margaret Mahler and Daniel Stern, and the psychologist Jerome Kagan used direct observations of mother infant interactions to reconceptualize the normal course of mental development as processes of acquiring individuality, intersubjectivity, and the ability to manage environmental novelty. Finally, basic researchers exemplified by Myron Hofer, Tom Insel, and Michael Meaney, have used rodent models to reveal how the mother regulates physiologic, neuroendocrine, and molecular biological processes of infant development. Together these advances have spawned a rich observationally-based research endeavor aimed at understanding the developmental origins of adult mental life and the environmental and innate determinants of deviant development leading to psychopathology. In the aggregate, these findings and concepts have permeated the current theory and practice of psychotherapy in general and psychoanalysis in particular through notions of attachment, affect attunement, and separation and individuation in the therapist patient relationship.

3. Learning and memory have now been understood at the cellular, molecular and genetic levels as processes of synaptic plasticity. Eric Kandel, the neurobiologist who pioneered this work in the relatively simple nervous system of the marine snail Aplysia and extended it to mice, is a psychiatrist with psychoanalytically based training. From the outset of his research, Kandel has been keenly aware of the significance of basic neurobiologic explanations of memory for the psychoanalytic endeavor, which holds memory to be the key to mental life and symptoms. On the heels of Kandel’s work Joseph LeDoux, Michael Davis, and others using rodent models have worked out the circuitry and cell biology of learned fear and anxiety, which are also key symptoms in many mental disorders.

Kandel has been pivotal in trying to join the hypotheses of psychoanalysis and the findings of neuroscience (Kandel 1999a). To do so, he has had to oppose those who would prefer to abandon psychoanalysis in their pursuit of neuroscience as well as those who would abandon neuroscience in their adherence to a strict interpretation of psychoanalysis. Beginning in 1979, a series of papers by Kandel (1999b) forcefully argued that scientific reductionism should be applied to our understanding of how the mind arises from the brain. Kandel’s own work demonstrates that a reductionistic understanding of neural processes can radically alter our conception of mental processes. He has extended this view by proposing that psychotherapy, which is a form of learning, must lead to detectable functional or structural alterations in the brain. Discovering the brain mechanisms of psychotherapy is thus seen as a deep problem whose answer must be sought through intellectual collaborations between biologically educated clinicians and clinically astute neurobiologists.

Referring to Kandel’s work in 1983 with aplysia, Cooper (1985) said:

The interaction of the environment and the adaptive responses of the organism can now be partially understood in terms of basic cellular neurobiology. The readiness with which an analyst attempts to affect the patient’s self or his brain organization through a new relationship or medication has philosophical and ethical connotations, and in the current absence of specific indications for either or both treatments, the treatment choice will reflect individual bias.

In this paper, Cooper also said that most analytic treatment carries with it a strong implication that it is a major analytic task of the patient to accept responsibility for his actions. In the psychoanalytic view, this responsibility is nearly total. We are even responsible for incorrectly or
exaggeratedly holding ourselves responsible. It is our job to change our harsh superegos, and it is our job to do battle with unacceptable impulses. However, it now seems likely that there are patients with depressive, anxious, and dysphoric states for whom the usual psychodynamic view of responsibility seems inappropriate and who should not be held accountable for their difficulty in accepting separation from dependency objects, or at least they should not be held fully accountable.

Studies on the Effectiveness of Psychotherapies: Overall Efficacy of Treatment

In practical terms, the scientific basis of psychotherapy must rest on a firm base of valid outcome research. Psychological therapy, perhaps best defined as “an interpersonal process designed to bring about modifications of feelings, cognitions, attitudes and behavior which have proved troublesome to the person who is seeking help from a trained professional” (Strupp 1978), now covers a very diverse set of activities which include at least six major approaches, each providing a model of human behavior as well as heuristic foci for interventions. These are as follows: (1) Psychodynamic psychotherapy, particularly concerned with how the experience of problematic internal states are encoded into relationship patterns that are evident in the person’s life and in relation to the therapist, (2) Behavioral and cognitive-behavioral therapy, rooted in classical as well as social learning theory but which now incorporates traditionally psychoanalytic ideas such as the influence of early life on patterns of thought, defensive avoidance of painful ideas, notions of helplessness, cognitive distortions, and discrepancy between an ideal and perceived self, (3) Interpersonal psychotherapy, which is primarily concerned with current social relationships and takes general educational as well as pragmatic approaches to relationship problems, (4) Strategic or systemic psychotherapies focusing on the family or institutional context that generates the problem behavior rather than any particular individual within the system, (5) Supportive and experiential therapies which facilitate self-awareness and reject the mechanistic philosophies of psychodynamic, systemic and behavioral therapies, and (6) Group therapies, which are appropriate to all the previous five types of interventions but represent an approach in their own right. The psychology of the therapeutic group is both the focus and a vehicle of the intervention.

Although all of these models provide etiologic formulations, their evidence base is limited. The best way of comparing these treatments is by RCTs where variables likely to influence outcome are controlled, for example, therapist experience, treatment length, etc. Increasingly, studies also ensure that treatments are carried out in a manner consistent with that standard. There are limitations to this approach, such as differences between the groups that occur despite randomization because of small sample sizes. Whereas the presence of an uncontrolled control group would provide an ideal benchmark, it is not ethically viable to withhold treatment in cases other than the very short-term psychotherapies. Increasingly, there are studies that compare psychosocial interventions with medication or the addition of psychosocial interventions to pharmacological treatment. The criteria most often used to establish the evidence base of a therapeutic approach for a particular condition is the replication of good quality RCTs with an independent group of investigators testing the same manualized treatment with the same diagnostic group.

Since Hans Eysenck (1952) expressed doubts about the overall efficacy of psychotherapy, there have been several meta-analyses of the psychotherapy research literature (Wampold 2001), as well as narrative reviews (Roth and Fonagy 2005), of hundreds of studies. Most studies report a considerable effect size (0.50–0.85) when treatment is contrasted with no treatment but much of this effect may be attributable to placebo effects. The major meta-analyses of therapy outcome have been drawn from rigorously-controlled studies (random assignment, careful specification of patient population, use of a treatment manual, raters naïve to conditions, statistical power adequate to examine the null hypothesis, and replication by independent investigators).

Space does not permit a review of the empirical status of psychotherapy for all mental disorders (for a comprehensive recent review: Roth and Fonagy 2005). To illustrate the nature of the evidence base, we will consider only the two most prevalent Axis I disorders, anxiety and depression, and the most commonly investigated Axis II condition, borderline personality disorder (BPD).

The literature on RCTs clearly identifies cognitive, behavioral, and cognitive behavioral treatments as highly efficacious in the treatment of anxiety disorders. The best effect sizes have been reported for cognitive therapy for panic disorder (Clark et al. 1994, 1999), cognitive therapy for post-traumatic stress disorders (Ehlers and Clark 2003, Ehlers et al. 2005), cognitive therapy for social phobia (Clark et al. 2006, Clark et al. 2003), CBT for generalized anxiety disorder (Dugas et al. 2003, Ladouceur et al. 2000), exposure and response prevention for obsessive-compulsive disorder (OCD) (McLean et al. 2001, Whitall et al. 2005) and exposure for specific phobias (Ost et al. 2001, Ost et al. 1997). Many of these studies used unstructured supportive treatment as a control for receiving clinical attention, that is, a placebo control.

There are a few RCTs of psychodynamic therapies for anxiety (e.g., Milrod et al. 2007) but there are some notable trials for depression (e.g., Shapiro et al. 1995). The National Institutes of Mental Health’s (NIMH) Treatment of Depression Collaborative Research Program (Elkin, 1994) is perhaps the most widely cited research program, which set a standard against which other studies could be judged. Patients were randomized to receive one of four interventions: cognitive-behavioral psychotherapy, IPT, imipramine plus clinical management (IMI–CM), or a placebo pill plus clinical management (PLA–CM). Clinical management consisted of a weekly meeting of 20–30 min to discuss medication, side effects, and the patient’s clinical status and when necessary, provide support, encouragement, and advice. Thus, both medication conditions (imipramine and placebo)
contained psychotherapeutic elements. Two hundred and the first nine patients, all moderately to severely depressed, entered the trial at three sites. Patients were assessed before treatment and at 4, 8, 12, and 16 weeks and followed up at 6, 12, and 18 months. At termination of therapy (Elkin et al. 1989), patients who received IMI–CM had the lowest symptom scores, PLA–CM the highest, and the two psychotherapies intermediate. Although the magnitude of these differences was not large, those who received IMI–CM and IPT were significantly more likely to have recovered at 16 weeks than those who had received PLA–CM. There were no significant differences between the two psychotherapies or between psychotherapies and IMI–CM. For patients with less severe depression, PLA–CM, which could be considered a “minimal support” intervention, was as effective as the active therapies. At the 18-month follow-up, no more than 25% of patients in any of the groups were recovered and without relapse. This key finding suggests that treatment of depression, whether pharmacologic or psychotherapeutic, requires a minimum duration to alter the underlying neurobiology.

The studies with the most rigorous methods demonstrate the efficacy of IPT and CBT. In the single trial comparing dynamic-interpersonal therapy (IPT) and CBT, there was no difference in efficacy. This broad equivalence in outcomes between distinct psychotherapies is an important result, suggesting that depression responds to a range of psychotherapeutic technique. Many large-scale careful studies, such as the Helsinki study (Knekt and Lindofrds 2004), found no difference between therapies. For example, there was no difference between psychodynamic psychotherapy and solution-focused psychotherapy, a systemic therapy. Overall, the generally-observed effect size for the psychodynamic treatment of anxiety is hard to estimate, and for depression the outcome of psychodynamic psychotherapy is comparable to CBT, although both therapies have only small to medium effects in the long-term (Leichsenring et al. 2001). In general “research therapy” appears more effective than clinical practice (Weisz and Jensen 1999). This may relate to methodological issues—among them the use of focused and structured manualized treatments, careful attention to ensure therapist adherence to protocol, participants recruited by advertisement rather than through clinical services, are screened for strict diagnostic criteria and severity levels, and subject to exclusion criteria.

Mechanisms of Psychotherapy

Outcome studies demonstrate that psychological treatments are effective, but which specific therapies are superior can only be addressed by “head to head” comparative trials. A number of such studies have compared a wide range of therapies, including psychodynamic, behavioral, cognitive, interpersonal, and client-centered methods. The results are surprisingly consistent: with notable exceptions (e.g., the superiority of CBT over IPT for the treatment of OCD and other anxiety disorders) research has failed to show that any one method is more potent than the others. For example, an ambitious comparison of transference focused psychotherapy, Dialectical Behavior Therapy (DBT) and supportive psychotherapy for BPD, showed little difference between these three forms of treatment after one year of therapy (Clarkin et al. 2007). In recent decades psychotherapy research has demonstrated repeatedly that a substantial proportion of the variability in therapeutic outcomes across trials is not well explained by differences between formally defined therapeutic procedures, differences between client groups, or (less well examined) the interaction between these two factors (e.g., Beutler et al. 2004, Beutler et al. 1994, Clarkin and Levy 2004, Garfield 1994). At the same time, controlled trials repeatedly demonstrate that the therapeutic relationship without theoretically coherent content is of little therapeutic value (Wampold 2001, Wampold et al. 2002). Thus, while the specific method applied does not generally correlate well with outcome, the consistent application of one method appears to be important.

In addition, no strong correlations have been found between outcome and the particular symptom that is
targeted by a specific type of therapy. For example, in a study of CBT, the extent of focus on ‘parental issues’, a theme generally viewed as more central to interpersonal psychodynamic therapies, was positively associated with outcome (Hayes et al. 1996). In a study of psychodynamic psychotherapy process and outcome, Piper (Piper et al. 1991) found that in sicker patients for whom the therapeutic alliance is shaky, the use of transference interpretations was associated with worse outcome, not better. Another study found a negative association between the number of transference interpretations and therapy outcome, indicating that the overuse of this technique frequently regarded by clinicians as essential to therapeutic success, may even be iatrogenic (Connolly et al. 1999). It is possible that the commonalities among psychotherapies, the ‘non-specific’ elements, are the effective ingredients, rather than their specific differences.

Frank and Frank (Frank and Frank 1991) proposed that a nonspecific factor common to all successful therapies is the therapist’s ability to instill their patients with hope. Yet a methodological review of child psychotherapy treatment studies between 1995 and 2004 (Jensen et al. 2005) found that recent research did not give adequate attention to nonspecific factors, including the effects of attention, positive regard and therapeutic alliance, as well as the effects of treatment dose, intensity, and actual processes mediating therapeutic change. One nonspecific component of all therapies that has been investigated is the quality of the therapist/patient relationship. Results revealed that a good relationship with one’s therapist is a crucial factor in the treatment’s outcome (Lambert 2004, Luborsky et al. 1988). Further, the therapeutic alliance is influenced by the quality of the therapist’s and patient’s attachment styles and quality of object relations, and in particular the therapist’s attachment security (e.g., Black et al. 2005, Eames and Roth 2000, Hilliard et al. 2000, Pinsker-Aspen et al. 2007). It is plausible that therapists with a secure attachment style approach the therapeutic relationship with greater openness and optimism which might be more effective in instilling hope in the client. Particularly, strong associations have been found between pretreatment expectations and the observed quality of the therapeutic alliance (Dew and Bickman 2005, Gaudiano and Miller 2006, Meyer et al. 2002, Zuroff and Blatt 2006). Clearly this evidence suggests that a good therapist/patient relationship is central to psychotherapy’s effectiveness.

**Therapist Factors in Therapy Outcome**

Wampold (2001) points out that evidence for common factors highlights the importance of the therapist and his or her skill.

In Kim et al.’s (2006) analysis of the NIMH’s Treatment of Depression Collaborative Research Project (NIMH TDCRP) dataset, 5–10% of the variance in outcomes was shown to be associated with therapists. In more naturalistic studies, the effects tend to be larger. Very large studies, with datasets of over 5,000 patients, consistently report large effects associated with therapists (Okiishi et al. 2006).

Therapist factors have been shown to be associated with the rate of improvement. For example, among 91 therapists treating nearly 2,000 patients, those therapists whose patients showed the most improvement had an average rate of improvement 10 times greater than the sample’s mean rate (Okiishi et al. 2003). This is consistent with other studies using a growth curve approach, where as much as 17% of the variance in rates of patient improvement has appeared to be attributable to the therapist (Lutz et al. 2007).

Some therapists are better than others, but what contributes to that quality? Beutler et al. (Beutler et al. 2004; Beutler et al. 1994) reviewed studies of the impact of therapist characteristics on outcome. The therapist’s age, gender, and ethnicity appear to have little or no impact on results, nor are there significant differences in outcome when therapist and client are matched on these variables. Assessment of the impact of therapist personality variables is limited, with some studies attempting post hoc atheoretical analysis, and others a more theory-driven approach, with no consistent or robust findings. There are indications that therapists with better levels of adjustment may have better outcomes, though there is inconsistency across studies.

Contrary to received wisdom, empirical findings suggest that the therapist’s experience does not help to predict outcome. Attempts to show the effects of experience have no conclusive results (Beutler et al. 2004, Propst et al. 1994). Wierzbicki and Pekarik’s (Wierzbicki and Pekarik 1993) meta-analysis of 125 studies found that there was no correlation between dropout rate and the therapist’s experience in years or professional qualifications—although there is some evidence that experience becomes a more important predictor of outcome with patients who are more disturbed.

**Long-term Psychotherapy**

Most psychoanalysts would consider that the aims and methods of short-term once-a-week psychotherapy are not comparable to a ‘full analysis’, or at least long-term psychodynamic psychotherapy involving more than one session per week usually for several years. What do we know about the value of intensive and long-term psychodynamic treatment and how do these results compare to short-term therapy? Here the evidence base becomes patchy and we cannot restrict the review to RCTs.

The Boston Psychotherapy Study (Stanton et al. 1984) compared long-term psychoanalytic therapy (two or more times a week) with supportive therapy for patients (once a week) with schizophrenia in a randomized controlled design. On the whole, patients who received psychoanalytic therapy fared no better than those who received supportive treatment. In a partial-hospital RCT (Bateman and Fonagy 1999, 2001) for BPD the psychodynamic arm of the treatment included therapy groups once a week plus individual therapy once or twice a week over an 18-month period. Compared with psychiatric treatment as usual, which consisted of less frequent visits to a psychiatrist and home visits by a nurse but no formal psychotherapy, showed the benefit of the psychodynamic therapy by 18 months, which continued over a further 18 months follow-up period. Another further controlled trial of intensive psychoanalytic treatment of children with chronically poorly controlled diabetes reported significant gains in diabetic control in the treated group relative to treatment as usual which was maintained at one year follow-up (Moran et al. 1991). Experimental single case studies carried out with the same population supported the causal relationship between interpretive work and improvement in diabetic control and physical growth (Fonagy and Moran 1991). The work of Chris Heinicke also suggests that
four or five sessions per week may generate more marked improvements in children with specific learning difficulties than a less intensive psychoanalytic intervention (Heinicke and Ramsey-Klee 1986).

The Stockholm Outcome of Psychotherapy and Psychoanalysis Project (Blomberg et al. 2001, Grant and Sandell 2004, Sandell et al. 2000) followed 756 individuals who received National Insurance-funded treatment for up to three years in psychoanalysis or psychoanalytic psychotherapy. The groups were matched on many clinical variables. Analysis four or five times a week had similar outcomes at termination when compared with one or two sessions per week of psychotherapy. During the follow-up period, psychotherapy patients did not change, but those who had had psychoanalysis continued to improve, almost to a point where their scores were indistinguishable from those obtained from a nonclinical Swedish sample (Sandell et al. 2002). While there are methodological problems with this study (e.g., lack of random assignment and an accelerated longitudinal design), the finding of a strong ‘sleeper effect’ restricted to the psychoanalytically treated group is unique.

The German Psychoanalytic Association carried out a major follow-up study (n = 401) of psychoanalytic treatments undertaken between 1990 and 1993 (Leuzinger-Bohleber et al. 2003, Leuzinger-Bohleber and Target 2002). Between 70 and 80 per cent of the patients (at an average of 6.5 years after the end of treatment) had achieved good and stable psychic changes. The evaluation of mental health costs showed fewer days’ sick leave on the part of the patients during the 6.5 years after long-term psychoanalytic treatment. In the absence of pre-treatment measures, it is impossible to estimate the size of the treatment effect.

The Research Committee of the International Psychoanalytic Association recently prepared a comprehensive review of North American and European outcome studies of psychoanalytic treatment (Fonagy et al. 2002a,b). The committee concluded that existing studies failed to demonstrate the efficacy of psychoanalysis relative to either alternative treatment or active placebo (placebo that generates an expectation of change). Studies showed a range of methodological and design problems, including absence of intent to treat controls, heterogeneous patient groups, lack of random assignments, failure to use independently administered standardized measures of outcome, etc. Nevertheless, the report, which ran to several hundred pages and describes more than fifty studies, did contain data that would encourage the development and execution of methodologically rigorous outcome studies of psychoanalysis. Another overview (Gabbard et al. 2002) suggested that psychoanalytic treatments may be necessary when other treatments proved to be ineffective. This study concluded that psychoanalysis appears to be consistently helpful to patients with milder disorders and somewhat helpful to those with more severe disturbances. More controlled studies are necessary to confirm these impressions.

**Conclusions**

Several conclusions can be drawn from the psychotherapy research literature. First, it appears evident that psychotherapy is effective in treating a wide variety of clinical conditions, with results often equal to those for drug-based treatments. Second, the affinity between patient and therapist (the so-called therapeutic alliance) may be a key factor in effective therapy. Third, although therapist skill is important in establishing this relationship, experience is not critical. Fourth, level of functioning and the ability to form a therapeutic alliance are better predictors of outcome than diagnosis. Fifth, evidence suggests that common factors and not specific techniques are crucial in therapy. Finally, it appears that most patients benefit from psychotherapy within the first six months of treatment, and that long-term therapy has no significant advantage over short-term therapy. However, psychodynamic psychotherapy may be associated with so-called ‘sleeper effects’ which means that the full benefit of therapy may not be evident until some months after the termination of the trial.

Research into psychotherapy will require further investigation to understand its mechanisms, especially into the therapeutic alliance, matching specific techniques with specific types or severity levels of problems, and the effect of dose and frequency of therapy.

**Biological and Neuroimaging Studies of Psychotherapy**

Most of the initial studies have focused on the hypothalamic pituitary-adrenal axis (HPA), specifically cortisol levels. Increased HPA activity, as reflected by increased serum or salivary cortisol levels, is considered to be the physiological expression of stress and so the primary experimental paradigm was to determine if there is a reduction in cortisol levels following a psychotherapeutic intervention (Gaab et al. 2002).

Studies of patient cohorts with varying pathologies including bullying behavior (Nickel et al. 2006), spider phobias (Straube et al. 2005), post-traumatic stress disorder (Mason et al. 2002), and generalized anxiety disorder (Jockers-Scherübl et al. 2006) receiving varied interventions including family therapy, mindfulness training (Marcus et al. 2003), and CBT, have consistently reported decreased post-treatment cortisol levels compared to baseline following a psychotherapy intervention.

Other variables that have been studied include heart rate, which was decreased from baseline following CBT in women who were under the stress of in-vitro fertilization procedures (Facchinetti et al. 2003). EEG sleep measures were different at baseline in responders vs. nonresponders to IPT in a sample of depressed patients Buyse et al. 1992) suggesting that sleep physiology is a predictor of recovery, rather than an indicator of a specific action of the therapy. Most intriguingly, a recent study assessed nerve growth factor (NGF) in patients with generalized anxiety disorder before and after treatment with CBT (Jockers-Scherübl et al. 2006). NGF has neurotropic actions within the central and peripheral nervous system but there is accumulating evidence that it also has immuno-modulatory functions as well. Serum levels of NGF are raised in stressful situations. Perhaps somewhat contrary to expectations, patients who responded to CBT had increases in serum NGR compared to patients who did not respond. This has been interpreted as an indicator of better stress management post-treatment but is open to other interpretations.

The use of functional positron emission tomography (PET), Functional magnetic resonance imaging (fMRI), and
structural magnetic resonance imaging (MRI), to demonstrate the effects of psychotherapy is relatively new and still needs significant development. Nonetheless, this approach has the potential to reveal which brain regions and networks are responsible for specific psychopathologies, and which register the effects of psychotherapy (see reviews: Roffman et al. 2005, Linden 2006). As a treatment, psychotherapy focuses on learning, unlearning, mastery and control, and it results in new evaluations and behavioral responses to both internal and external stimuli. The use of imaging to study psychotherapy has taken three approaches: (1) the documentation of metabolic (PET) or structural (MRI) effects of psychotherapy alone or psychotherapy compared to medication treatment in anxiety and depressive disorders; (2) the use of fMRI to study responsiveness to charged stimuli before and after treatment, for example, exposure to spider images in patients with spider phobia; and (3) the use of imaging techniques to validate concepts that are central to dynamic psychotherapies, for example, the demonstration of unconscious effects.

The imaging studies to date demonstrating the effects of psychotherapy have methodological problems in common, including small sample sizes, the fact that comparator studies (medication vs. psychotherapy) are often not randomized, and that data analysis does not always compare responders to nonresponders.

The first studies of psychotherapy used \(^{18}F\) fluoro-deoxyglucose (FDG) PET to assess metabolic changes associated with CBT for the treatment of OCD (Baxter et al. 1992). Baseline studies of patients with OCD have reported increased activity in the right caudate and a significant correlation between caudate, orbital frontal cortex and thalamic activity (Baxter et al. 1987, 1988). In the studies of CBT, responders showed a decrease in right caudate activity and importantly the significant correlation between the caudate, thalamus and OFC was significantly attenuated. These effects were observed not only for CBT but also for fluoxetine treatment suggesting the important possibility that the effects of therapy on brain function depend on response, not on modality, even for those modalities as disparate as a psychological intervention and a drug (Baxter et al. 1992, Brody et al. 1998). The same finding of decreased activity in the right caudate after treatment with CBT was also reported in a second study of 22 patients with OCD using other methodologies to measure cerebral blood flow (Nakatani et al. 2003). In summary, though the studies are few and the numbers are small, there has been a surprisingly consistent finding of hyperactivity in the right caudate at baseline in particular with obsessive/compulsive disorder, and significant decrease in activity in this area in patients after psychotherapy and, in at least one study, after selective serotonin reuptake inhibitor (SSRI) medication treatment as well.

One study used MRI to determine whether there is a structural difference in the thalamus after 12 weeks’ CBT in patients with OCD (Rosenberg et al. 2000). There was no change in thalamic volume, which is perhaps not surprising given the relatively brief time between baseline and post-treatment measurement. The documentation of structural brain changes may require either a longer time between baseline and post-treatment measurements and/or different imaging methodologies to detect meaningful but small changes in hypothesized regions of interest.

Three studies have compared psychotherapy to medication in patients with major depressive disorder, one study comparing IPT to venlafaxine using single photon emission computed tomography (SPECT) (Martin et al. 2001), one study comparing IPT to paroxetine using FDG PET (Brody et al. 2001), and one study comparing CBT to paroxetine also using FDG PET. (Goldapple et al. 2004) Perhaps due to the heterogeneity of most samples of patients meeting criteria for major depressive disorder and/or due to limitations in study design including small sample sizes, the findings of these studies have been inconsistent and at times contradictory. Nonetheless, Goldapple et al. proposed (Goldapple et al. 2004), a cogent theoretical model to explain the results of their study in which they compared paroxetine to CBT treatment for depression, namely that, in contrast to the findings of Baxter et al. described above, improvement can occur in different ways. In Goldapple et al.’s (2004) study, the two treatment modalities seemed to produce opposite changes in responders, specifically that in the pre-frontal cortex there was decreased activity after CBT but increased activity after paroxetine treatment, whereas in the limbic areas the reverse was reported, namely increased activity after cognitive behavioral treatment and decreased activity after paroxetine treatment. The hypothesis offered is that, at least in the case of depression, psychotherapy has a top-down effect, which means that cortical effects influence sub-cortical structures, whereas pharmacotherapy has a bottom-up effect, that is from limbic and sub-cortical areas through to the cortex. Preclinical studies of medications with antidepressant action have documented a series of effects, including aminergic reuptake inhibition, auto-regulatory desensitization, and receptive remediative second-messenger and neurotropic signaling effects, which have been interpreted as a bottom-up chain of events. In clinical studies that have assessed functional changes in patients who have responded to antidepressant medication, the most consistently reported findings are changes in the frontal cortex involving the normalization of both frontal over-activity and under-activity, which may result from bottom-up effects such as those found in animal models. In contrast to the bottom-up effect of medications, the hypothesized mechanism by which CBT and other psychotherapies are effective in the treatment of depression is generally thought to involve directly modifying attention and memory functions involved in cognition and maladaptive processing of external and internal stimuli; this is thought primarily to be a top-down mechanism.

The second approach to exploring the impact of psychotherapy is to use fMRI to measure response to symptom provocation before and after treatment. There are two studies of patients with arachnophobia, in which the patients are shown standardized images of spiders both before and after treatment with CBT (Straube et al. 2005). There were significant decreases in activity post-treatment, but the localization of the decreased activity was somewhat different for the two treatment studies, with decreases in right dorsal lateral pre-frontal cortex vs. the insula and thalamus, respectively.

In the third approach, imaging techniques have been used to validate the brain correlates of unconscious processes, which are central to the theory and practice of psychoanalysis, but for which to date the evidence has been
limited to behavioral correlates and verbal communications in psychodynamic treatment. For example, a central tenet of psychodynamic theory is that unconscious affects are crucial determinants of behavior. In an innovative paradigm, Etkin et al. (2004) measured baseline anxiety in a group of normal subjects and then exposed them to a series of fearful faces. It is known that fearful faces will reliably stimulate activity in the amygdala, but the unique aspect of this experiment was that the faces were presented in two different ways, one that stimulates conscious activity and another that is registered without conscious awareness. The unconscious processing was achieved through a procedure called backward masking, in which the fearful face is presented too briefly to be recorded consciously, and is then immediately followed by the presentation of a neutral image. If the subject reacts to the backward masked fearful face, this is interpreted as an unconscious response. There was an increase in amygdala activity after the presentation of fearful faces, which correlated with the baseline trait anxiety scores. However, this was only found when the fearful faces were processed unconsciously. This method has the potential to test differential effects of a psychotherapy that targets conscious thoughts such as cognitive therapy vs. one that targets unconscious processes such as transference focused psychotherapy.

**Conclusion**

For years, psychodynamic and psychoanalytic paradigms dominated the theory and practice of psychotherapy. The psychoanalytic community’s initial rejection of empirical research was reversed by (1) the clearcut effectiveness of pharmacologic treatments, (2) observational research on normative and pathological infant and childhood behavior which forced a reexamination of fundamental concepts of development, and (3) the advent of powerful techniques for a reductionist neurobiology of complex mental functions such as learning, memory and affect. These advances have motivated new interest in psychotherapy and have spurred the development of methods for demonstrating the effectiveness of psychotherapy and ultimately for understanding its mechanisms of action at the levels of interpersonal, intrapsychic, and neural function. It is now accepted that any form of psychotherapy, including dynamic psychotherapy, must have its effectiveness established by rigorous clinical trials as a prerequisite for the investigation of its mechanisms of action. Furthermore, the study of the effects of psychotherapy offers a unique opportunity to illuminate the fundamental problem of the relationship between the mind and the brain.

Introduction

The key features of schizophrenia are psychotic, or so-called positive symptoms (especially delusions and hallucinations), negative symptoms, and cognitive dysfunction (see chapter on clinical manifestations of schizophrenia). These symptoms are often accompanied by fluctuating symptoms of affective and psychomotor dysregulation such as depression, anxiety, hostility, and agitation (Figure 19–1). These components of the disorder vary in their form, time of presentation, intensity, and course from patient to patient, often independently of each other. Treatments affect them differently. It is not yet clear if these three symptom clusters result from a single pathophysiological process or whether their underlying biological bases are distinct (Meltzer 1979, Kirkpatrick et al. 2001). New evidence indicates that neurobiological features are shared between bipolar disorder with psychotic features and schizophrenia—disorders that have been regarded as separate since the work of Emil Kraepelin (1856–1926, Adler and Strakowski 2003).

There is extensive evidence for the hypothesis that schizophrenia is a neurodevelopmental disorder, which continues to unfold throughout life. It is thought to result from genetic and environmental factors, and to lead to abnormalities in neural systems that are critical substrates for the assessment of sensory input, information processing and storage, and social interaction. As discussed in Chapter 14, genetic factors play a major causal role in schizophrenia, with multiple genes contributing to the pathogenesis and determining response to treatment. Epigenetic mechanisms bridge the gap between environment and the genetic predisposition (Petronis et al. 1999). Stressful life events, which activate the hypothalamic-pituitary-adrenal axis and stimulate the release of various brain neurotransmitters, especially dopamine and norepinephrine, are also thought to be a key factor in the etiology of schizophrenia (Phillips et al. 2006). Gender differences in schizophrenia (Patel et al. this volume) suggest a possible role for sex hormones in the etiology of schizophrenia. Environmental factors may include drugs of abuse such as cannabis, stimulants such as amphetamine, and psychotomimetic agents such as phencyclidine, which interact with the genetically determined vulnerability to trigger the disorder, usually in late adolescence and early adulthood, but also in childhood (Hambrecht and Hafner 2000, Millan 2005).

The neurobiology of schizophrenia includes both structural and functional abnormalities. The structural changes in the brains of patients with schizophrenia have been studied with classical neuropathological methods, and more recently, brain imaging (Jarskog et al. 2007). The pioneering work of Carlsson and Seeman focused on the role of dopamine in the pathophysiology of schizophrenia’s psychotic symptoms. However, dopamine’s role is now understood within the framework of other neurotransmitters, especially GABA, glutamate and serotonin, which regulate the activity of dopaminergic neurons and the response of neurons to dopamine in several regions of the brain including the prefrontal and anterior cingulate cortex, the medial temporal lobe, and the thalamus (Coyle 2006).

This chapter provides a broad overview of several of the advances in the understanding of the neurobiology of schizophrenia. Evidence for the neurodevelopmental hypothesis will be presented first. Abnormalities in key neurotransmitter systems and neural circuits will be considered. The use of intermediate phenotypes (endophenotypes), which are measurable traits that may be more proximal to the underlying genetic vulnerabilities, are also discussed.
Neurodevelopmental Concept
The neurodevelopmental model of schizophrenia posits that schizophrenia results from abnormalities in development that begins in utero and continues through infancy, adolescence, and young adulthood. The initial processes predate the onset of clinical symptoms, and are thought to be caused by a combination of genetic and environmental factors (Singh et al. 2004, Jarskog et al. 2007). Individuals who later develop schizophrenia have higher rates than healthy subjects of pre- or perinatal insults with minor physical anomalies, as well as minor deviations in motor, cognitive, and social development. There are at least two major epochs during which developmental brain insults are believed to heighten the risk of schizophrenia: (1) pre- and perinatal and (2) disturbances in brain maturation during late adolescence (Feinberg 1982, Mathalon et al. 2003). Initial postmortem studies appeared to support the early neurodevelopmental model, they reported abnormalities in neuronal migration and organization were fetal in origin (Jakob and Beckmann 1986, Akbarian et al. 1993). Subsequent and more reproducible observations of reduced neuronal size and arborization (Selemon and Goldman-Rakic 1999), which could have developed later in life, indicated that the pathophysiological processes involved in schizophrenia need not be restricted to the pre- or perinatal period. This is in agreement with brain imaging studies that reveal progressive changes for early onset as well as adult onset patients. Indeed, candidate genes for schizophrenia include some that are involved in neurodevelopment across different developmental periods, e.g., DISC-1, reelin, neuregulin-1, dysbindin-1, and AKT-1 (Arnold et al. 2005). Variability in the number and combination of mutations of these and other neurodevelopmental genes could provide the basis for the heterogeneity of schizophrenia.

Pre- and Perinatal Risk
A large number of studies have found a relationship between obstetric complications (OCs) and the onset schizophrenia. The two main reasons for the interest in OCs are the availability of relevant data from objective and contemporaneous medical records and the specificity of the nature and timing of such events. A meta-analysis of population-based data found significant increases in three main categories of OCs: (1) complications of pregnancy such as bleeding, pre-eclampsia, diabetes, and rhesus blood group incompatibility; (2) abnormal fetal growth and development including low birth weight, congenital malformation, and small head circumference; and (3) complications of delivery, in particular, asphyxia, uterine atony, and emergency Cesarean section (Cannon et al. 2002a, 2002b). The increase in overall risk for schizophrenia conferred by such events seems genuine but small, with a pooled odds ratio for the effect of OCs on the subsequent development of schizophrenia about 2.0. The role of obstetric complications may be greater for individuals with greater impairment, or early onset (before age 18). Rather than being direct causal agents for schizophrenia, obstetrical events could be markers for some other neurodevelopmental or environmental factors, particularly since OCs are themselves multifactorial in origin. For example, low birth weight and small head circumference reflect retardation of fetal growth, but almost any factor affecting the fetus adversely will retard its growth.

Bleeding in pregnancy, pre-eclampsia, and delivery complications are thought to result in chronic hypoxia or acute asphyxia (Cannon et al. 2002a, 2002b). Cannon and co-workers (Rosso et al. 2000) argue that ischemic damage leads to neuronal loss in temporal brain regions such as the hippocampus, which are known to be involved in schizophrenia (see discussion of premorbid risk below) and are sensitive to hyoxic insults. The association between schizophrenia and serologically confirmed in utero influenza, rubella, and respiratory infections (Brown and Susser 2002) may reflect abnormal maternal immune response, consistent with the possible role of early infection. Several studies have reported elevation of pro-inflammatory cytokine levels (Ashdown et al. 2006).

Premorbid Risk
Follow-back, cohort, and special population studies show that the premorbid history of patients with adult onset schizophrenia is replete with a variety of subtle...
neurodevelopmental abnormalities beginning in childhood (Cannon et al. 2002a, 2002b).

**Early Developmental Delays/Skeletal Muscle and Motor Abnormalities**

Children who went on to be diagnosed as having schizophrenia were found to have abnormal upper limb movements (Walker et al. 1994). Neuromotor abnormalities have been found to be, along with cognition, the most reproducible biological marker for schizophrenia in high-risk family studies (Owens and Johnstone 2006). Although they are not specific for schizophrenia, they do support the neurodevelopmental hypothesis. Two major British cohort studies, the National Survey of Health and Development and the National Child Development study, found delays in the speech and motor development of British children born during specified periods in 1946 and 1958, respectively. Such abnormalities were most obvious for motor milestones before the age of 2 years and for language development between the ages of 2 and 15 years. The increased risk was associated with deficits across several developmental domains, including achievement of age-appropriate motor, social, and intellectual milestones, perhaps reflecting some underlying general risk (Jones et al. 1994, Isohanni et al. 2004).

Retrospective and clinical studies show that speech and language deficits increase in frequency and severity with earlier age of onset (Hollis 1995). Finally, motor abnormalities appear to be trait markers for schizophrenia as they have been noted in both drug-free patients and in their unaffected first-degree relatives (McCreadie et al. 2003).

A variety of abnormalities in the morphology of skeletal muscle, the physiology of motor nerves, and subterminal motor nerve branching, as well as the loss of motor neuron units leading to increased size of surviving motor units, have been reliably reported in patients with schizophrenia and their first-degree relatives (Meltzer 1976, Goode et al. 1977, Flyckt et al. 2000).

**Social and Cognitive Development**

A variety of studies including the British cohort studies mentioned above document poor peer relationships, social isolation, social anxiety, and a gender effect with boys being more disruptive and girls being more withdrawn. These studies again indicate increasing risk over a whole range of developmental measures suggesting some underlying general risk for psychosis rather than a threshold model (Jones et al. 1994).

General cognitive ability, assessed between the ages of 7 and 17 years either by formal cognitive tests or by using educational achievement as a proxy measure, is lower in preschizophrenic children compared to their healthy peers (reviewed in Rapoport et al. 2005). Decline in general intellectual function (between ages 4 and 7 years) and persistently low scores in cognitive testing during early childhood (between ages 3 and 11 years) show some specificity for schizophrenia and schizophrenia spectrum disorders, while emotional and social problems seem to be nonspecific indicators of a variety of different adult psychiatric outcomes (Cannon et al. 2002a, 2002b).

**Premorbid Psychopathology**

Kim-Cohen et al. (2003) found a diversity of premorbid psychopathology in patients who went on to develop schizophrenia by including Diagnostic and Statistical Manual (DSM) diagnostic data in a prospective study of a representative birth cohort of 1037 individuals participating in the Dunedin Multidisciplinary Health and Development Study. In this study, 53% of individuals who were diagnosed as having schizophrenia or schizophréniform disorder (a schizophrenia-like syndrome that lasts 6 months or less) at age 26 had been evaluated at ages 11, 13, 15, 18, 21 years. Unlike mood and anxiety disorders, which were generally preceded by similar types of affective disorder in childhood, schizophréniform disorder (and subsequently schizophrenia) was preceded by an array of juvenile diagnoses including anxiety, depression, conduct disorder or oppositional defiant disorder, and attention deficit hyperactivity disorder. At age 11, nearly 15% of the sample reported some delusional or hallucinatory experience (Poulton et al. 2000). At 26, 25% of the group with the most prominent childhood psychotic symptoms was diagnosed with a schizophrénia-related psychotic illness using modified DSM-IV-TR criteria for schizophrenia and schizoaffective disorder designed to minimize misdiagnosis. By adulthood, 70% of these individuals developed schizophrenia-related symptoms that did not satisfy diagnostic criteria. This important finding contradicted the widely held belief that psychotic symptoms occurring in nonpsychotic children have little predictive power for the future development of schizophrenia. These data are also inconsistent with the concept that psychotic symptoms associated with schizophrenia are possible only when higher order association systems ‘come on line’ later in development.

**Premorbid Cognitive Impairment**

Individuals at risk for schizophrenia have significant cognitive impairment before the onset of psychosis, especially memory and learning. Although most of these impairments seem nonspecific, they nevertheless support a neurodevelopmental hypothesis. The level of cognitive impairment is less than in the first episode of schizophrenia (Keefe et al. 2006, Owens and Johnstone 2006). Neurocognitive deficits appear to be an early predictor or risk for the development of schizophrenia or other psychotic disorders (Keefe et al. 2006).

**Brain Imaging Studies during Development**

The developmental abnormalities discussed above are paralleled by developmental disturbances in brain development. Longitudinal studies in adult onset patients provide evidence for progressive changes in grey matter, including cortical atrophy, although the number of studies and sample sizes are small, and the follow-up periods are relatively short (DeLisi 1999, Mathalon et al. 2003, Shenton et al. 2001). These findings may reflect subtle abnormalities in brain plasticity that result from a continuing neuropathologic process or systemic physiological fluctuations. Pantelis et al. (2005) examined a group of individuals before and after the onset of psychosis and also reviewed other longitudinal studies. Longitudinal studies of first episode patients (mean age between 26 and 30 years) have provided evidence of increases in ventricular volume over a 2–4 year period.
period, and bilateral decreases in frontal lobe gray matter volume. Similar declines in frontal lobe volume and posterior superior temporal gray matter volume have also been reported in chronic schizophrenic patients (mean age 39 years) over a 4 year period (Mathalon et al. 2001). These findings suggest both early and late phases of brain tissue loss.

Studies of Childhood Onset Schizophrenia (COS)
Variability in age of onset must be explained by any proposed etiology of schizophrenia. Patients with childhood onset schizophrenia generally have the most severe illnesses and exhibit a high rate (85%) of early developmental delays (Nicolson and Rapoport 1999). Nicolson and Rapoport found no increased obstetrical risk in those with an early age of onset.

Premorbid diagnoses for the childhood onset patients included high rates of anxiety disorders (57%) and pervasive developmental disorders (26%). There was no predictive specificity of these earlier diagnoses for schizophrenia, as elevated rates for these disorders were also seen in individuals with other adult psychiatric outcomes. These varied premorbid diagnoses most probably reflect the variability in the developmental phenotypes produced by the risk genes. Alternate hypotheses include locus heterogeneity, varied environmental stressors or toxins, and "noise" in the developmental system (Singh et al. 2004).

Pediatric Brain Imaging Studies Relevant to Schizophrenia
In the last decade, there has been a concerted effort to obtain normative structural data for human brain growth across the understudied child and adolescent age period. The anatomic development of subcortical structures, including the amygdala, basal ganglia, and thalamus, has been shown to be relatively complete by late childhood, with cortical regions having substantially longer developmental trajectories. Grey matter volume increases in late childhood and decreases during puberty, following a consistent "back to front" pattern (Gogtay et al. 2004). Based on studies of primates and human cerebral cortical development, these volumetric changes are thought to reflect initial overproduction, followed by selective elimination and structural alterations of dendritic synapses (Zeccevic et al. 1989, Huttenlocher and Dabholkar 1997). Medial aspects of the temporal lobe mature early while the lateral regions representing higher integrative areas are among the last to mature (Gogtay et al. 2004).

Anatomic MRI studies of childhood onset schizophrenia show grey matter reduction and ventricular enlargement typical of that seen in adults (Frazier et al. 1996a, 1996b). Longitudinal data from subjects with early onset schizophrenia show striking progressive changes. Thompson et al. (2001) reported that the earliest deficit was profound parietal grey matter loss, which then moved anterior into the temporal lobes, sensorimotor and dorsolateral prefrontal cortices, and frontal eye fields. This difference was diagnostically specific, as it is not seen in children with atypical and affective psychoses who were receiving the same medications. In the same cohort of patients, there was also progressive increase in ventricular and decrease in hippocampal volume (Giedd et al. 1999). As shown in Figure 19–2, these cortical changes appear to be exaggerations of the normal cortical development.

Genetics and Developmental Neurobiology
The genetics of schizophrenia is covered in detail in Chapter 13 Merikangas and Karayiorgou. Only certain key neurodevelopmental aspects of the genetics of schizophrenia will be highlighted here. Converging data indicate that there are abnormalities in the brains of patients with schizophrenia related to synapse formation, stabilization, function, and elimination (Levitt 2005). These, in turn, are consistent with genetic pathways which have been identified in genome-wide association as well as candidate gene studies (Harrison and Weinberger 2005, Ross et al. 2006). As discussed below, risk genes for schizophrenia are associated with premorbid neurodevelopmental impairment and/or MRI abnormalities in the growth of brain grey and white matter. Finally, very early onset illness is associated with a 10% rate of cytogenetic abnormalities, a rate similar to that seen in autism (Rapoport et al. 2005).

Gene Expression Throughout Development
Eukaryotic cells use a variety of post-transcriptional mechanisms to regulate gene expression. By developmentally regulated and tissue-specific alternative splicing, multiple protein forms can be produced from a single gene. It appears that many, if not most, genes act at more than one developmental period, with different levels of expression and even different sites in the brain most active at different developmental time points (see Rapoport et al. 2005). These expression patterns are now being studied for schizophrenia susceptibility genes (eg, for the 22q11 region; Maynard et al. 2003).

Knowledge of how the identified susceptibility genes for schizophrenia contribute to the disease’s pathogenesis is in its early stages. Some of them have multiple roles in normal function during adulthood and development that could be relevant. For example, neuregulin (NRG1), one of the first known susceptibility genes for schizophrenia (Stefansson et al. 2002), is involved in neuronal migration and connectivity, cell signaling, and myelination (Corfas et al. 2004). Schizophrenia associated single nucleotide polymorphisms (SNPs) alter the mRNA transcript levels for at least two isoforms of NRG1, Type I and Type IV, suggesting that differential isoform expression accounts for the role of NRG1 in schizophrenia (Law et al. 2006). The NRG1 Type IV isoform is of particular interest because it is brain specific and is particularly abundant in the fetal brain. One of the schizophrenia risk SNPs is associated with differential activity of Type IV’s upstream 5' promoter region (Tan et al. 2007). Other important candidate genes for schizophrenia, including DISC-1, reelin, and dysbindin-1, appear to have critical roles in both brain development and/or neural integrity. For instance, DISC-1, the expression of which is increased during neuronal development (Schurov et al. 2004), is believed to be involved in the regulation of neuronal migration and neuronal maturation, as well as modulation of synaptic transmission and plasticity (Porteous et al. 2006). Dysbindin appears to be a key regulator of glutamatergic transmission and prefrontal functioning, and may be important to the glutamatergic
deficit which appears to occur in schizophrenia (Maier et al. 2006).

Genetics and Endophenotypic Markers
Family, twin, and adoption studies involving schizophrenic patients have revealed high heritability, estimated at 80% (Cardno et al. 1999, Sullivan et al. 2003). This does not exclude a role for nongenetic factors: the concordance rate for schizophrenia in monozygotic twins is only 50% (Cardno et al. 1999). Nevertheless, there is now convincing evidence that a combination of risk genes contributes to the overall susceptibility to developing schizophrenia.

The search for schizophrenia’s neurobiological basis has been slowed by the disorder’s complex inheritance and clinical phenotype, as noted above. This has led to investigations of disease characteristics that are themselves heritable, more quantifiable than clinical symptoms, and presumed to be proximal to the disease’s neurobiological causes. Because these characteristics, termed “endophenotypes,” are themselves heritable and tend to be highly penetrant, they are also present in unaffected family members. Additional criteria for endophenotypes that have been proposed (Gottesman and Gould 2003) are that endophenotypes must (1) manifest as traits, i.e., features that persist independently of the presence or severity of disease symptoms, (2) cosegregate with the illness within families, and (3) occur at a higher rate among non-affected family members than that of the general population.

Several endophenotypes for schizophrenia have been proposed. One group of proposed endophenotypes are deficits of sensorimotor control and reflex inhibition. Specific sensorimotor control and inhibition phenomena that are impaired in schizophrenia include smooth pursuit eye movements, antisaccade eye movements, P50 auditory evoked responses, and pre-pulse inhibition. Approximately 50% of patients with schizophrenia have abnormalities in smooth pursuit eye movements, which are independent of the severity of psychotic symptoms, attentional state, or antipsychotic drug treatment (Lee and Williams 2000). A specific component of smooth pursuit eye movements, predictive pursuit, has high concordance within sibling pairs in which the proband has schizophrenia. This finding suggests that predictive pursuit eye movements represent a heritable neurobiologic trait related to risk for schizophrenia (Hong et al. 2006). The antisaccade task requires the subject to inhibit the reflexive saccadic pursuit of a target and direct her gaze to the mirror image opposite position. Both are impaired in individuals with schizophrenia.
and their unaffected relatives (Calkins et al. 2004) and are thought to reflect dysfunctional interactions between areas of the frontal, temporal, or parietal cortices and the striatum.

Two indicators of sensorimotor gating, the P50 event-related potential (ERP) and pre-pulse inhibition (PPI), consistently demonstrate deficits of inhibition in schizophrenia. Inhibition of the P50 auditory ERP is deficient in patients with schizophrenia (Bramon et al. 2004) and unaffected relatives (Turetsky et al. 2007). In this paradigm, an auditory stimulus produces an evoked response after approximately 50 msec. The response to a second stimulus given 500 msec later is normally inhibited, as indicated by a reduced ERP. In schizophrenia the inhibition of the second response is absent, which is interpreted as an abnormality of a basic sensory gating mechanism that is associated with deficits of sustained attention and vigilance (reviewed in Martin and Freedman 2007). The PPI paradigm makes use of the eye blink startle reflex to a sudden loud tone. When a softer tone precedes the loud one, the startle response is inhibited, an effect that depends on the interaction of a cortico–striatal–pallidal–pontine circuit with the primary startle reflex. The inhibition of startle by the pre-pulse is impaired in both schizophrenics and their relatives (Kim et al. 2005). PPI deficits have been related to clinical parameters in patients with schizophrenia including positive and negative symptoms and specific types of cognitive deficits (Geyer et al. 2001).

Another type of endophenotype for schizophrenia involves abnormalities in the detection of novel or discrepant sensory information. Patients with schizophrenia, compared to normal controls, show an attenuated response to another ERP, the P300 response to novel, unexpected, or emotionally laden stimuli (Ford 1999). This wave form, occurring 300 ms after the stimulus, represents a composite of temporally overlapping separate cortical responses that include aspects of directed attention, working memory, and the attribution of salience to the stimulus (Turetsky et al. 2007). Its reduced amplitude is a particularly robust physiologic phenomena in schizophrenia (Turetsky et al. 1998). There is also strong evidence that unaffected family members of schizophrenic individuals have decreased P300 amplitudes (Kimble et al. 2000, Weisbrod et al. 1999). In a related paradigm, mismatch negativity, a “novel” auditory stimulus is included in a series of uniform auditory stimuli. A normal response is the generation of a negative electroencephalographic signal, an effect that is blunted in patients with schizophrenia (Michie 2001). Like PPI, abnormalities in mismatch negativity have also been related to cognitive deficits in schizophrenia (Baldenweg et al. 2004).

Cognitive Dysfunction

Deficits in cognitive functioning in schizophrenia are now viewed as core features of the disorder and are believed to directly reflect specific abnormalities in brain development or functioning. For example, working memory dysfunction in schizophrenia has been associated with reduced activation of dorsolateral prefrontal cortex (Levy and Goldman-Rakic 2000). The cognitive deficits also appear to have a greater impact on functional outcome than psychotic symptoms such as hallucinations and delusions (Green et al. 2000). The domains that are most impaired include attention, working memory, language skills, and executive functioning, with the greatest impairments in verbal learning and memory (Bowie and Harvey 2005). Although no specific cognitive deficits is pathognomonic of schizophrenia, spatial working memory in particular may be heritable (Cannon et al. 2000) and over-represented in relatives of schizophrenic patients (Myles-Worsley and Park 2002, Saperstein et al. 2006). Thus, the cognitive deficits characteristic of schizophrenia may qualify as an endophenotype for the illness.

The cognitive dysfunction in schizophrenia occurs independently of the severity of positive symptoms (Addington et al. 1991), and is only weakly correlated with negative symptoms (Buchanan et al. 1994, Harvey et al. 1996). Impairments in cognition persist even when psychotic symptoms remit, and are apparent even before the first onset of psychotic symptoms. Treatment with typical neuroleptic medications, on average, does not result in significant improvement of cognitive deficits in schizophrenia, whereas most studies suggest that atypical antipsychotics appear to exert a modest beneficial effect (Woodward et al. 2005) (although a recent multicenter comparison showed slight and approximately equal benefits to cognitive function for both atypicals and typicals (Keefe et al. 2007)). Conversely, while treatment with typical neuroleptics can worsen psychomotor performance for some patients, these drugs do not consistently appear to worsen cognitive performance; thus, cognitive impairment in schizophrenia is not caused by treatment with typical neuroleptic drugs (Hoff et al. 1999). As further evidence of this, neuropsychological function deficits have been identified among medication-naive schizophrenic patients at the first break (Brickman et al. 2004).

The course of cognitive deficits has been examined in both cross-sectional and longitudinal studies. Deficits identified at baseline in these studies were stable over long-term follow up, with no clear evidence of declining cognitive function (Townsend and Norman 2004). Whereas attention, executive function, memory, and psychomotor speed have improved in some studies and declined in others, most studies suggest that impairments in cognitive functioning are stable and persist in spite of improvements in positive and negative symptoms.

Neurochemical Abnormalities in Schizophrenia

Dopamine

The identification of dopamine (DA) as a neurotransmitter and the ability of chlorpromazine to block DA receptors (Carlsson and Lindqvist 1963) led to the DA hypothesis of schizophrenia, which suggested that increased dopaminergic transmission was causally related to schizophrenia (Rossum 1966). This concept received strong support from (1) the extremely tight correlation between clinical doses of a wide range of antipsychotic drugs and their potency to block DA D2 receptors (Seeman et al. 1975, Creese et al. 1976) and (2) studies confirming the psychotogenic effects of DA enhancing drugs such as amphetamine and methamphetamine (Meltzer and Stahl 1976). The mesolimbic dopaminergic pathway, with cell bodies in the ventral tegmentum, and terminals in the ventral striatum, which includes the nucleus
accumbens, the striatal terminalis, and the extended amygdala, was viewed as the specific region of the brain that produced the positive symptoms, delusions, and hallucinations (Meltzer and Stahl 1976). The nigrostriatal dopaminergic pathway includes projections from the substantia nigra pars compacta to the dorsal striatum and is involved in motor function. Typical antipsychotic drugs, of which haloperidol is the most commonly used, are thought to ameliorate the positive symptoms via the mesolimbic pathway but to cause extrapyramidal symptoms by their ability to block DA D₂ receptors in the dorsal striatum.

About one-third of patients with schizophrenia who are given amphetamine or methylphenidate, another indirect DA agonist develop a marked increase in psychotic symptoms, although some patients actually improve, particularly with regard to negative symptoms (Janowski et al. 1974, Meltzer and Stahl 1976, Lieberman et al. 1987). Marked and exaggerated decreases in [¹¹C] raclopride and [¹²³I] iodobenzamide (IBZM) binding in the striatum occur after acute amphetamine exposure in patients with schizophrenia relative to matched control subjects, indicating increased dopamine release (Abi-Dargham 2004). These effects have been demonstrated in first-break, drug naïve subjects, as well as those who have received antipsychotic drug treatment.

The exaggerated DA response effects after amphetamine exposure were also shown to be greater in magnitude among schizophrenic patients who were experiencing a psychotic exacerbation compared with those who were clinically stable (Laruelle et al. 1999). Numerous efforts to directly identify excessive output of DA by patients with schizophrenia using cerebrospinal fluid or plasma levels of DA metabolites, homovanilllic acid and dihydroxyphenylacetic acid, have produced equivocal results. On the post-synaptic side, PET and postmortem studies of D₁ receptor density in the striatum of patients with schizophrenia originally produced mixed results (Laruelle 1998).

Imaging studies have also shown higher baseline occupancy of D₂ receptors in patients with schizophrenia who were experiencing an acute exacerbation of psychosis, relative to healthy control subjects. Moreover, recent PET scanning with increased resolution, which allows compartmentalization of the striatum, unexpectedly found that the increase in basal D₂ receptor occupancy is highest in the dorsal striatum. Since higher pretreatment synaptic dopamine levels predict a better response to atypical antipsychotic drug treatment, this suggests that the dorsal striatum may be as important for generating symptoms as the ventral striatum (Abi-Dargham et al. 2000). Together, these studies provide further support for striatal dopaminergic excess as a key component of the pathophysiology of particularly positive signs and symptoms in schizophrenia, as well as the importance of striatal DA D₂ receptor blockade in the pharmacological activities of antipsychotic drugs. All typical and most atypical antipsychotic drugs have significant D₂ antagonist or partial agonist effects at the central DA D₂ receptor.

The importance of prefrontal DA transmission at D₁ receptors (the main DA receptor in the neocortex) for optimal PFC performance was an important step in moving beyond interest in the D₂ receptor and schizophrenia, despite the failure of D₁ antagonists to improve psychosis (Goldman-Rakic et al. 2000) and the finding that D₁ receptor affinity did not discriminate between typical and atypical antipsychotic drugs (Meltzer et al. 1989). The view that too little or too much cortical DA receptor stimulation can lead to impaired cognition has been particularly influential (Goldman-Rakic et al. 2000). Indeed, results from in vivo molecular imaging studies of D₁ receptor availability indicate a relationship between cognitive functioning and D₁ receptor levels in the prefrontal cortex in patients with schizophrenia, although, due to the use of a variety of ligands, the findings have been inconsistent (Abi-Dargham and Moore 2003).

Increasing awareness of the importance of enduring negative and cognitive symptoms in this illness, their independence from positive symptoms, and the inability of typical antipsychotic drugs to improve these symptoms, led to an appreciation of the severe limitations of the DA hypothesis. Clearly, increased dopaminergic activity in the limbic system was an insufficient basis for schizophrenia as a whole, and perhaps not even for psychosis, in that about one-third of all patients with schizophrenia fail to respond to typical antipsychotic drugs, regardless of dose. In addition, numerous types of preclinical and clinical data suggested that cognitive impairment and negative symptoms might arise from deficits in dopaminergic activity in the prefrontal cortex (PFC) (Meltzer and Stahl 1976, Davis et al. 1991, Knable and Weinberger 1997, Rao and Moller 1994). Eventually, a more nuanced hypothesis emerged: hyperactive subcortical mesolimbic projections (resulting in hyperstimulation of mesolimbic D₁ receptors and positive symptoms) and hypoactive mesocortical DA projections to the PFC (resulting in hypostimulation of D₁ receptors, negative symptoms, and cognitive impairment) supplanted the original formulation of the DA hypothesis (Davis et al. 1991). These hypotheses are based, in part, upon an appreciation of the evidence that prefrontal cortical dopaminergic activity, when diminished, may increase the activity of subcortical DA neurons which innervate the ventral striatum (Pycock et al. 1980, Jaskiw et al. 1990, Tzschentke 2001). There is some evidence of an association between low levels of homovanillic acid levels (HVA), the major metabolic byproduct of DA, and severity of negative symptoms and cognitive deficits (Davis et al. 1991). However, most of the evidence to date is indirect. Supporting evidence includes the observed changes in D₁ receptor levels in the PFC and the observation that atypical antipsychotic agents, which are believed to be more effective for treating cognitive dysfunction and negative symptoms than typical neuroleptics (Moller 2003, although see the recent CATIE study, Keefe et al. 2007), appear to increase DA release in the prefrontal cortex (Kuroki et al. 1999) and hippocampus (Chung et al. 2002). Direct evidence comes from immunohistochemical studies that show a decrease in the number of tyrosine hydroxylase positive terminals in the prefrontal cortex (Akil et al. 1999).

**Serotonin**

A role for serotonin (5-hydroxytryptamine, 5-HT) in the etiology of schizophrenia was first postulated because of the structural similarity between 5-HT and the hallucinogenic drug, lysergic acid diethylamide (LSD; Gaddum 1954). LSD, as well as other hallucinogens such as mescaline and psilocybin were subsequently found to be 5-HT₂A and 5-HT₂C agonists. Stimulation of 5-HT₂A receptors is predominantly responsible for the hallucinogenic effect of these agents (Gresch et al. 2002). Although these drugs produce mainly...
visual hallucinations, which are far less common than auditory hallucinations in schizophrenia, the hypothesis of a role for 5HT in schizophrenia has proved useful. Genetic mutations of serotonin system genes, primarily those coding for 5-HT2A and 5-HT1A receptors, have been reported to be more common in patients with schizophrenia or linked to the action of atypical antipsychotic drugs (Reynolds et al. 2005, Norton and Owen 2005). The more tolerable side effects and possibly greater efficacy of the atypical antipsychotics, such as clozapine, compared to the typicals has been attributed to their relatively more potent antagonism of 5-HT2A than of D2 receptors (Meltzer 1989, 1991). This pharmacologic profile prompted the development of “balanced” 5-HT2A-D2 antagonists as antipsychotics, e.g., risperidone, olanzapine, quetiapine, ziprasidone, and laurisdione.

The anatomic distribution and physiologic actions of 5HT receptors suggest what role these receptors play in the therapeutic effects of atypical antipsychotics. Excitatory 5-HT2A and inhibitory 5-HT1A receptors are located on glutamatergic pyramidal neurons and GABAergic interneurons in the cortex and hippocampus, which enables them to modulate glutamate release in the terminal regions of these neurons (Meltzer 1999, Millan 2000). 5-HT2A receptors are also located on the cell bodies of DA neurons in the ventral tegmentum and substantia nigra, while 5-HT1A receptors are also found on the cell bodies of 5-HT neurons in the raphe nuclei (reviewed by Meltzer et al. 2003). Clozapine and related atypical antipsychotic drugs combine high potency 5-HT2A receptor antagonism with relatively lower potency D2 receptor blockade (Meltzer et al. 2003) and direct or indirect agonism of 5-HT1A (Ichikawa et al. 2002b). Aripiprazole, which substitutes partial D2 receptor agonism for D2 antagonism, is also a 5-HT2A antagonist and 5-HT1A partial agonist and, thus, fits the clozapine model fairly well. In preclinical models, atypical antipsychotic drugs, but not typical neuroleptics, are associated with increases in cortical DA efflux, an effect which is due, in part, to 5-HT2A antagonism combined with low D2 receptor antagonism (Meltzer et al. 2003). It is hypothesized that the ability of atypical antipsychotic drugs to preserve or even enhance cortical DA release may be one mechanism by which these drugs may ameliorate negative symptoms and improve cognition. Because 5-HT exerts tonic inhibition of DA release via 5-HT2A heteroreceptors located on DA cell bodies in the substantia nigra (Nocjar et al. 2002), the 5-HT2A receptor antagonism associated with most atypical antipsychotic drugs may release these cells from tonic inhibition by 5-HT. Such an effect may bring about relative preservation of dopaminergic tone in the nigrostriatal dopaminergic pathway, and limit the potential for EPS.

**Glutamate**

Four main lines of evidence suggest a dysfunction of the glutamate system, and in particular \(N\)-methyl-\(D\)-aspartate (NMDA) receptor dysfunction, in schizophrenia. First, NMDA receptor antagonists such as phencyclidine (PCP) or ketamine have been shown to produce positive, negative, and cognitive symptoms in healthy individuals and exacerbate preexisting symptoms in patients with schizophrenia even after one single use (Javitt and Zukin 1991, Krystal et al. 1994). Alterations in certain neurophysiological measures, including N1 event-related potential and mismatch negativity generation, P50 gating, and pre-pulse inhibition (PPI) (discussed below), are among the most consistent and robust indices of brain dysfunction in schizophrenia and can be observed in humans after single administration of NMDA antagonists (Umbricht et al. 2000). Second, NMDA dysfunction can lead to the dopaminergic alterations observed in schizophrenia with imaging techniques: an acute challenge with ketamine can produce increased subcortical dopamine release (Kegeles et al. 2002) and chronic recreational use of ketamine leads to alterations in dorsolateral prefrontal cortical D1 receptor density similar to that observed in schizophrenia (Narendran et al. 2005). Third, certain genes that have recently been associated with an increased risk for schizophrenia such as neuregulin 1, GRM3, and DISC-1, can influence the function of modulatory sites on the NMDA receptor or synaptic glutamate transmission (Hahn et al. 2006, Moghaddam 2003). For instance, the Type II metabotropic glutamate receptor encoded by GRM3 regulates the expression of glutamate transporters on glial cells, has a major influence on extracellular glutamate levels (Aronica et al. 2003). Fourth, postmortem studies have shown numerous alterations in glutamate receptor binding, transcription, and subunit protein expression in the prefrontal cortex, thalamus, and hippocampus of subjects with schizophrenia (Meador-Woodruff and Healy 2000). These studies overall lend strong support to the concept of broad alterations in NMDA transmission in schizophrenia and suggest these may lead to additional downstream effects on the actions of DA and GABA.

Some evidence links certain aspects of NMDA receptor-mediated dysfunction to DA or 5HT. Thus, haloperidol pretreatment reduced impairments in executive cognitive functions produced by ketamine infusion in normal volunteers, but not the psychosis, perceptual changes, negative symptoms, or euphoria (Krystal et al. 1999). Systemic administration of PCP and ketamine increase the efflux of 5-HT in the mPFC of rats. The atypical antipsychotics clozapine and olanzapine, as well as ritanserin, a 5-HT2A receptor antagonist, and prazosin, an alpha1-adrenoceptor antagonist, but not the typical D2 antagonist antipsychotic haloperidol, reversed the PCP- and ketamine-induced increase in 5-HT efflux. PCP-induced disruption of sensory gating was blocked by the selective 5-HT2A receptor antagonist, M100907, as well as clozapine (Javitt 2004). These findings implicate 5-HT in NMDA receptor hypofunction and again emphasize the importance of 5-HT receptor blockade in the action of the atypical antipsychotic drugs.

**GABA**

A variety of abnormalities in indices of GABA neurotransmission have been reported in the dorsolateral prefrontal cortex (DLPFC) of patients with schizophrenia (Lewis et al. 2005). Postmortem studies have consistently shown reduced expression of the mRNA for the 67 kDa isoform of glutamic acid decarboxylase (GAD67), the rate-limiting enzyme in GABA synthesis, and its corresponding protein, in the DLPFC (Lewis et al. 2005, Akbarian and Huang 2006). GAD67 mRNA expression is undetectable in a subpopulation (about 25–30%) of GABA neurons in cortical layers 2–5 in the brains of patients with schizophrenia. These neurons are among the calcium-binding parvalbumin (PV)-containing GABA neurons in the DLPFC, which appear
Acetylcholine (ACh)

ACh is involved in schizophrenia at multiple levels via both nicotinic receptors (nAChR), which are ionotropic and muscarinic receptors (mAChR), which are metabotropic. People with schizophrenia have abnormalities in the expression of central nervous system nicotinic receptors, and the alpha-7 subtype. Deficits in P50 measures, discussed below, of auditory gating in schizophrenics and their first-degree relatives, are associated with alpha-7 subunit gene promoter polymorphisms. Decreased alpha-7 nicotinic receptor binding has been noted in the reticular nucleus of the thalamus, the hippocampus, and various regions of the cortex. P50 auditory gating has been linked to the chromosome 15q14 locus of the alpha-7 nicotinic acetylcholine receptor gene (CHRNA-7) (Freedman et al. 1997).

The muscarinic system has also been implicated in schizophrenia directly by postmortem findings of decrease in some subtypes (mostly M1) in brain regions of patients with schizophrenia (DLPFC and hippocampus) (Crook et al. 2001). These findings, coupled with indirect pharmacological data, support a role for the muscarinic system in the pathophysiology and treatment of cognitive symptoms (Raedler et al. 2006). Atypical antipsychotic drugs enhance the efflux of ACh in the cortex (Ichikawa et al. 2002a) and hippocampus (Chung et al. 2002). Muscarinic receptor agonists such as scopolamine, xanomeline, and N-desmethylclozapine, the major metabolite of clozapine, are of considerable interest at the current time as novel treatments for psychosis as well as to improve cognition in schizophrenia (Weiner et al. 2004, Li et al. 2005).

Pathology of the Plasma Membrane

Several abnormalities in phospholipids and other cellular membrane fatty acids have been found in patients with schizophrenia (Berger et al. 2006, Yao and Reddy 2003). Schizophrenia-associated abnormalities in receptor-mediated signaling of neurotransmitters may be secondary to membrane phospholipid dysfunction (du Bois et al. 2005). Certain membrane phospholipids, particularly arachidonic acid and docosahexaenoic acid, are critical secondary messengers involved in dopaminergic, serotonergic, glutamatergic, and cholinergic signal transduction (both Bois et al. 2005, Rana and Hokin 1990), particularly in response to environmental demands. Finally, arachidonic acid is also a secondary messenger in the signaling of several neurotransmitter factors including brain-derived neurotrophic factor (BDNF) and nerve growth factor (NGF) (du Bois et al. 2005). Thus, phospholipids play an important role not only in cellular signaling, but also in neuronal growth and integrity during early neural development and beyond.

Clinically, abnormalities in antioxidant defense systems, which prevent formation of *OH, have been reported in both medicated and unmedicated patients with schizophrenia (Yao et al. 2001). Reduced levels of arachidonic acid and docosahexaenoic acid in erythrocytes have been associated with predominantly negative symptoms of schizophrenia, but were not associated with severity of positive symptoms (Glen et al. 1994). Specific membrane phospholipid dysfunction may come as a result of damage secondary to oxidative stress through the generation of free radicals (Yao et al. 2001). There is accumulating evidence for the involvement of free radical toxicity, free radical-induced mutations, and failure of antioxidant defense systems in the pathogenesis of schizophrenia that may be genetically determined (reviewed by Rao and Balachandran 2002, Yao et al. 2001). In one neurodegenerative model of schizophrenia, increased apoptosis may be triggered by increased oxidative stress, leading to progressive synaptic dysfunction and clinical deterioration over time (Margolis et al. 1994). Increased oxidative stress may lead to phospholipids peroxidation and generation of free radicals. In an experimental model of schizophrenia, mice exposed to NMDA antagonists showed an increase in the generation of hydroxyl free radicals (*OH), the primary biochemical species driving lipid peroxidation, in posterior cingulate and retrosplenial cortex (Zuo et al. 2007). In rats exposed to the NMDA antagonist, MK-801, increased levels of prefrontal malondialdehyde, an indicator of lipid peroxidation, were increased compared with control animals (Ozyurt et al. 2007).

Interestingly, administration of omega-3 essential fatty acids, which have been associated with a possible protective effect against lipid peroxidation, along with MK-801, resulted in significantly decreased levels of prefrontal malondialdehyde in rodents, compared with animals who were given MK-801 alone (Ozyurt et al. 2007), suggesting that omega-3 fatty acids and other antioxidants may have an adjunctive therapeutic or preventive role in schizophrenia (Mahadik et al. 2006). Clinical studies have demonstrated positive correlations between omega-3 essential fatty acids and improved clinical outcomes, though results are still preliminary (Werneke et al. 2006). Free-radical-mediated lipid peroxidation has also been implicated in the adverse effects of antipsychotic drugs—namely, tardive dyskinesia (TD) and clozapine-induced agranulocytosis. For example, schizophrenic patients treated with antipsychotics who were also diagnosed with tardive dyskinesia had lower plasma levels of antioxidant enzymes compared with non-TD patients (Zhang et al. 2007). In addition, malondialdehyde levels were positively correlated with the severity of TD. Clozapine has been found to significantly increase production of reactive oxygen species and expression of pro-apoptotic...
genes in neutrophils (Fehsel et al. 2005), suggesting that the well-known risk of agranulocytosis associated with clozapine treatment may be related to induction of oxidative stress in the context of increased pro-apoptotic gene expression.

**Neural Circuits**

It is apparent that multiple key brain regions are implicated in the pathophysiology of schizophrenia, including the prefrontal cortex, limbic structures (namely, hippocampus and anterior cingulate gyrus), striatum, and thalamus. There have been various abnormalities in cellular architecture, neurochemical activity, and functional activity demonstrated for each brain area. These can be expected to affect connectivity and circuitry necessary for the normal processing and flow of information within and between these brain regions. For example, alterations in connectivity within the DLPFC can cause working memory impairment, while diminished or dysregulated pyramidal cell outputs to other brain regions, such as the striatum, will in turn produce abnormalities in mesolimbic and nigro-striatal dopaminergic function (Bunney and Bunney 2000). Since these key regions are interconnected by several neuronal circuits, alterations in one region are likely to affect one or more of the others, leading to alterations in the functions subserved by the circuit.

The cortico–striato–pallido–thalamo–cortical (CSPFC) pathways represent five parallel circuits that connect cortical and subcortical regions of brain that are involved in regulating cognition, impulse control, affect, motivation, and drive (Alexander et al. 1986). They consist of closed loops that, in general, start in a particular area of cortex, synapse first in the striatum, then in the globus pallidus/substantia nigra, followed by the thalamus, and finally back to the cortex. In schizophrenia, neuropathological and in vivo data point to impaired dorsolateral prefrontal cortex (DLPFC) function and disrupted connectivity between it and striatal as well as other components of the cortico–striatal–thalamo–cortical loop. For instance, in neuropathological studies of the DLPFC of subjects with schizophrenia, pyramidal neurons exhibit decreased soma size, dendritic length, and spine density. Multiple alterations related to GABAergic transmission within the DLPFC have also been reported. The thalamus in patients with schizophrenia appears to have decreased cell numbers and fewer projections to the DLPFC, consistent with structural neuroimaging studies which show reduction in thalamic volume (Clinton and Meadow-Woodruff 2004).

Functional and molecular neuroimaging studies have documented abnormally reduced activity in DLPFC in patients with schizophrenia both at rest and during a variety of cognitive tasks, especially those that involve working memory and executive function. Prefrontal cortical activity at rest appears to be inversely related to severity of negative symptoms (Liddle et al. 1992). In addition, poor cognitive performance was associated with increased availability of cortical dopamine D1 receptors as measured by PET, a possible result of D1 receptor upregulation resulting from low prefrontal dopaminergic tone (Abi-Dargham et al. 2002). A link between DLPFC hypofunctioning and exaggerated striatal DA release has also been demonstrated. Thus, reduced DLPFC activation during a working memory task predicted increased striatal DA release in a cohort of schizophrenic subjects (Meyer-Lindenberg et al. 2002).

Exactly how problems with DLPFC outflow to underlying brain structures occur is a matter of active investigation. As previously discussed, there is evidence of cytoarchitectural disruption of pyramidal cells, the principal mode of excitatory cortical output, among patients with schizophrenia. The axon terminals of the chandelier class of GABA neurons form distinctive arrays, termed “cartridges,” which provide inhibitory input exclusively to the axon initial segment of pyramidal cells. This enables them to regulate the excitatory output of pyramidal neurons and, consequently, to substantially affect the patterns of neuronal activity within the PFC. The relative density of the GABA membrane transporter, GAT-1, of chandelier neurons, but not other populations of GABA neurons, was decreased by 40% in the PFC of schizophrenic subjects compared with matched groups of normal control and nonschizophrenic psychiatric subjects (Woo et al. 1998). The chandelier neurons may be responsible for maintaining the synchronized firing of pyramidal neurons (Lewis et al. 1999). This type of synchronized firing oscillates in the gamma band range of ~30–80 Hz (Lewis et al. 2005). In the DLPFC, these gamma oscillations increase during tests of working memory (Lewis et al. 2005); thus, impairment of pyramidal firing synchronization in DLPFC secondary to malfunction of these GABAergic interneurons could contribute to deficits in working memory. In addition, these PV-containing GABAergic interneurons express NMDA and D1 receptors in nonhuman primate brain; thus, GABAergic dysfunction and aberrant cortical pyramidal excitatory output may result from reduced excitatory glutamatergic (from other cortical pyramidal neurons) or dopaminergic input (from basal forebrain structures), or both. Cho et al. (2006) studied induced gamma-band activity during a cognitive task which requires cognitive control processes in association with prefrontal cortical activations in imaging studies. Electroencephalographic studies have demonstrated that the ability to generate greater gamma band coherence during talking is disrupted in patients with schizophrenia (Ford and Mathalon 2005). Patients with schizophrenia did not show the induced gamma band activity in prefrontal areas that normal controls did when increased cognitive control demands were needed. Disturbances in gamma-band activity in patients correlated with illness symptoms.

Dysfunction within the limbic system has also been implicated in the pathophysiology of schizophrenia. Based in part on its reciprocal connections with frontal cortex, the anterior cingulate cortex is involved in cognition (especially attention), affective control, motivation, and drive (Tamminga et al. 2000). Neuropathological studies have shown reduced density of GABAergic interneurons in anterior cingulate of patients with schizophrenia (Benes et al. 2001), while neuroimaging studies have found reduced functional activity of the anterior cingulate cortex both at rest and during cognitive challenge (Yue et al. 2002; Heckers et al. 2004). There is also evidence of impaired hippocampal structure and functioning in schizophrenia. Specifically, many studies have reported subtle reductions in hippocampal volume in patients with schizophrenia, as well as in their first-degree relatives, compared with controls. There is also evidence of white matter changes and synaptic disorganization in the hippocampi of patients with schizophrenia and, thus, impaired connectivity...
Neuropathology and Structural Brain Changes

Pathological studies have documented cytoarchitectural abnormalities in both cortical and subcortical regions in postmortem schizophrenic brain, including reduced glial density and proliferation, loss of cortical gray matter volume, and white matter abnormalities including volume loss (Arnold 1999). These changes may be responsible, in part, for earlier observations of decreased cortical thickness and total brain weight associated with schizophrenia. As yet, there is no clear evidence of neuronal loss or other markers (e.g., reactive gliosis) that would suggest that schizophrenia is primarily a neurodegenerative disease (Halliday 2001). Other quantitative histopathological studies have, on the other hand, documented schizophrenia-associated reductions in dendritic spines and total dendritic length (collectively referred to as “neuropil”), as well as deficits in synaptic markers (e.g., synaptophysin, complexins) in cortical pyramidal neurons (Glaniz and Lewis 2000, Pierri et al. 2001). Although they are of considerable interest, these subtle cytoarchitectural changes lack diagnostic specificity for schizophrenia. Findings from gene array studies have documented reduced expression of synaptic gene products, providing further evidence for schizophrenia-associated abnormalities in synaptic connectivity and transmission (Dean 2000).

Structural magnetic resonance imaging (MRI) and computerized tomography (CT) studies of individuals with schizophrenia have shown morphological alterations in nearly every brain region (Henn and Braus 1999). The most consistent findings include reduced whole brain volume, reduced prefrontal and medial temporal gray matter volume, reduced thalamic volume, and enlargement of lateral and third ventricles, relative to normal controls. Two findings, lateral and third ventricular enlargement and medial temporal lobe volume reduction, have been the most frequently replicated and have achieved significant meta-analytic effect sizes (Elkis et al. 1995, Honea et al. 2005, Shenton et al. 2001, Wright et al. 2000). Most of these morphological changes have been documented at the first episode of psychotic illness, and are thus not believed to occur as an artifact of antipsychotic drug treatment. Importantly, reduced temporal volume has been correlated with the severity of positive symptoms including auditory hallucinations and disordered thought (Onitsuka et al. 2004).

Several of these aforementioned structural abnormalities are present before the first onset of psychotic symptoms (Kumari and Cooke 2006), and may be progressive (Ho et al. 2003). The progressive course of structural changes with MRI may follow a similar trajectory to several of the neurocognitive changes reviewed earlier, and may also contribute to the deterioration in clinical course commonly observed in the treatment of schizophrenia. Specifically, further increases in ventricular volume identified in patients with schizophrenia were observed during longitudinal follow-up (Ho et al. 2003). In addition, studies of first-episode schizophrenic patients have documented progressive loss of total cerebral gray matter volume, with pronounced loss occurring in frontal and superior temporal cortex (Gur et al. 1998).

White matter abnormalities have been found in structural neuroimaging studies, particularly diminished total white matter volume among patients with schizophrenia relative to normal controls (Walterfang et al. 2006). Specific volume reductions have been reported in white matter zones underlying frontal, temporal, partial, and occipital cortices. The clinical significance of these findings and their response to antipsychotic drug treatment is relatively uncertain. A technology that is based on MRI, diffusion tensor imaging (DTI), has been used to measure abnormalities in the integrity of white matter tracts themselves. Disruptions in white matter tract integrity measured by DTI have been associated with deficits in both declarative memory and executive-type functioning among patients with schizophrenia (Kubicki et al. 2007). Schlosser et al. (2007) analyzed both fMRI (during a working memory task) and DTI data in 18 patients with schizophrenia and 18 controls. DTI analyses revealed reductions of fractional anisotropy (FA), an indicator of cerebral white matter integrity, in the right medial temporal lobe adjacent to the right parahippocampal gyrus. In addition, fMRI revealed prefrontal, superior parietal and occipital relative hypoactivation in patients versus controls. This was accounted for by reduced prefrontal activation during the encoding phase of the task, but not during maintenance or retrieval phases. This study also found a positive correlation in patients between frontal FA reduction and fMRI activation in regions in the prefrontal and occipital cortex. Thus, the combined use of fMRI and DTI demonstrated altered structure-function relationships in schizophrenia. They also suggest an important relationship between anatomical changes in a frontal-temporal anatomical circuit and functional alterations in the prefrontal cortex.

Electrophysiological Abnormalities

Functional Brain Imaging

Functional MRI (fMRI) studies of schizophrenia have measured regional cerebral blood flow (rCBF) as an index of metabolic activity in areas of interest at rest and while performing specific cognitive tasks. In general, no specific, consistent disease abnormalities in cortical activity, as estimated by rCBF, in the resting state, have been identified in patients with schizophrenia (Liddle et al. 1992). However, during active auditory hallucinations, rCBF is increased in several areas, including ventral striatum, medial temporal lobe, and superior or middle temporal gyrus (Kircher and Thienel 2005). This suggests that auditory hallucinations are perceived as real to patients because they occur in structures that mediate normal language.

Abnormalities in rCBF in patients with schizophrenia compared with normal controls have been reported during the performance of specific cognitive tasks. In particular, during working memory tasks, reduced frontal and DLPFC activation has been observed in patients with schizophrenia (Glahn et al. 2005). Deficits in DLPFC activation have also been reported among patients with schizophrenia during problem solving and other executive functioning tasks, while
deficits in activation of other regions of prefrontal cortex have been documented during tasks that require selection of responses based on emotional content and probability of reward. Poor prefrontal activation has also been demonstrated in a cohort of individuals who were in the prodromal stage of schizophrenia, providing further support for prefrontal cortical dysfunction as a core element of the disorder (Morey et al. 2005).

While patients with schizophrenia show diminished cortical activation during some cognitive tasks, they also appear to demonstrate normal or even enhanced DLPFC activation when performing other tasks, where performance is also impaired relative to healthy controls (Weinberger and Berman 1996). When performance of DLPFC-related cognitive tasks are equalized between patients with schizophrenia and healthy controls, patients with schizophrenia show a relative increase in cortical activation, suggesting that more DLPFC activation may be required for patients with schizophrenia for the same level of performance on a task. This decrease in cortical efficiency has been hypothesized as being a result of abnormal dopaminergic transmission (reviewed earlier), or impaired connectivity and synchronization with other brain regions (Heinz et al. 2003).

Abnormalities of cortical activation as measured by fMRI have been documented in other brain regions. Studies of memory and auditory processing have reported abnormal cortical responses, often in the form of overactivity, in medial and superior temporal lobes, including the hippocampus and parahippocampal gyrus (Davidson and Heinrichs 2003, Zakzanis et al. 2000). In particular, certain aspects of hippocampal-dependent memory functioning (encoding of new information and retrieval of previously stored information) are impaired in patients with schizophrenia. This observation has been paired with observed patterns of hippocampal hyperactivity at baseline along with impaired modulation of hippocampal activity during retrieval. Other regional changes in response to memory or executive function challenges have been reported in the striatum, thalamus, and cerebellum.

Many of the key results from fMRI studies reviewed above have been supported using other functional neuroimaging techniques. For example, PET has been successful in demonstrating increased glucose utilization in the temporal cortex during auditory hallucinations in patients with schizophrenia (Silbersweig et al. 1995). These results are consistent with those from fMRI studies already cited. Magnetic resonance spectroscopy (MRS) studies have also provided further evidence of prefrontal deficits in schizophrenia (Abbott and Bustillo 2006). Using 31P-MRS, increased membrane phospholipids degradation and impaired synthesis have both been reported in the frontal lobes of patients with schizophrenia, while 1H-MRS has been used to demonstrate increased levels of frontal lobe glutamine and glutamate which are reduced by treatment with atypical antipsychotic drugs. Finally, diffusion tensor imaging (DTI) studies have provided further evidence of white matter disorganization in frontal and temporal subcortical zones, as reviewed earlier. Specifically, both increased and decreased white matter bundle connectivity has been documented for patients with schizophrenia relative to normal controls, as well as in actively hallucinating patients relative to normal controls and patients who were not actively hallucinating (Hubl et al. 2004). These results provide further evidence of

Abnormalities in the coordination of neural activity between key brain regions, such as the prefrontal and temporal cortices.

Conclusion

Even though we cannot claim to fully understand the etiology or pathophysiology of schizophrenia, there has been considerable progress in understanding its neurobiology during the past few decades. The major advances include the following findings: (1) multiple genes confer vulnerability to develop schizophrenia; among the candidate genes are those that regulate the development of the nervous system and the maintenance of synaptic integrity; (2) there is evidence for overlap between the genetic determinants of schizophrenia and bipolar disorder. As a result, genetic testing for vulnerability to develop schizophrenia or bipolar disorder may become possible; (3) the neurodevelopmental hypothesis bridges the gap between these risk genes and the schizophrenia phenotype. This hypothesis posits important roles for environmental factors, ranging from intrauterine events to adolescent stresses and neurodegenerative processes in the overall pathologic process; (4) there is now a consensus that there is a decrease in the neuropil of patients with schizophrenia but not neuronal loss in selected areas of the brain, including the prefrontal cortex; (5) abnormalities in GABAergic neurons have been consistently identified, even though this information has not yet translated into more effective or safer treatments for schizophrenia; (6) glutamatergic pyramidal neurons in the cortex and hippocampus, with strong serotonergic inputs which regulate their firing, have emerged as the most important candidates for causing the cognitive disturbance that is a hallmark of schizophrenia, even if it is not specific for it. Based largely on the strong similarity between some aspects of schizophrenia and the effects of NMDA receptor antagonists, glutamate is now considered perhaps the most relevant neurotransmitter for understanding the pathophysiology of the disorder.

Recent advances in basic and clinical research in the anxiety disorders converge on several areas: (1) critical distinguishing clinical features of these disorders, (2) the neurobiological basis of anxiety disorders in human populations, (3) animal studies that define cause–effect relations between neural function and anxiety or fear behaviors, and (4) studies of etiology that provide an increasingly clear understanding of the developmental trajectories that define vulnerability for anxiety disorders. Additionally, an emerging area of research is studies of behavior, cognitive function, and neural activity in clinical populations to define the clinically relevant effects of pharmacological and psychotherapeutic treatments. This chapter summarizes and synthesizes current research approaches to anxiety disorders and attempts to show the impact of this research on current trends in their diagnosis and treatment. Currently, there is increasing emphasis on relevant clinical dimensions, as opposed to more traditional categorical approaches, and an emerging view of anxiety as a set of cognitive–perceptual disorders that derive from alterations in neural systems critical for attentional processes and emotional regulation.

Overview
The characterization of anxiety disorders in Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, (DSM-IV) (American Psychiatric Association 1994) was based on the assumption that a number of disorders shared essential features in the domain of fear or anxiety that merited their inclusion in one overarching category. At the same time, DSM-IV emphasized that these conditions differed sufficiently from one another that they deserved to be regarded as distinct disorders. Anxiety disorders are extremely common. The National Comorbidity Survey Replication (Kessler et al. 2005) found that almost 30% of adults in the US reportedly suffer from at least one of these conditions over the course of their lives.

Historically, anxiety disorders have been subdivided into two basic categories: (1) conditions that occur in response to aversive events (reactive states of anxiety) and (2) those conditions that are associated with the constant and unrealistic anticipation of danger. Another important and somewhat overlapping distinction common in clinical research is between a high level of anxiety that is stable over time (trait anxiety; Spielberger 1971) compared with those that characterize a short-term condition (state anxiety). As described in the following historical review, the diagnosis of anxiety disorders reflects these distinctions. The modern era of clinical research that more clearly describes specific and relevant symptoms of patient populations has led to the improved diagnostic categories in DSM-IV. Nevertheless this categorical approach remains limiting, due in part to the fact that the reactive and anticipatory anxiety, as well as the state and trait anxiety, are not nearly as distinguishable as once thought. For example, a panic attack represents a clear example of anticipation as well as contemporary state of anxiety. The repeated occurrence of panic attacks worsens subsequent attacks such that each attack is a product of the current state of anticipation associated with the reaction to previous attacks. The form of the disorder changes accordingly such that patients suffering repeated panic attacks will often develop severe agoraphobia. Moreover, panic attacks do not occur randomly in the population, and as described below in sections on vulnerability, panic disorder (PD) is a familial condition in which affected individuals show an enhanced, premorbid vulnerability that is often defined by what we would consider as increased trait anxiety. A similar interaction between premorbid vulnerability (trait) and the occurrence of trauma commonly defines patients with chronic posttraumatic stress disorder (PTSD) (see below).
Similarly, clinical experience indicates that the severity of any form of anxiety disorder, including obsessive-compulsive disorder, will worsen in response to stress. Trait and state, reaction and anticipation are invariably linked and thus blur diagnostic distinctions.

Research in psychology, neuroscience, and clinical psychiatry and psychology has greatly advanced our understanding of anxiety disorders. Neuroimaging of human populations together with relevant animal models have led to remarkably a coherent description of the neural circuits that mediate the expression of fear-related emotional states. Studies of human and nonhuman subjects have led to an understanding of the developmental origins of vulnerability for anxiety disorders. Animal models suggest that vulnerability emerges as a function of gene–environment interactions occurring within cells in the neural circuits that underlie fear and anxiety. These are critically important advances. Thus, the ultimate treatment of individual patients, even those expressing a common set of symptoms, may be determined by etiology as well as a knowledge of the underlying patterns of neural activity. This may be equally true for psychotherapy and pharmacologically-based interventions (Etkin et al. 2005b).

History and Clinical Picture of Anxiety Disorders

History

Classifications of psychiatric disorders pertaining to anxiety that predated Diagnostic and Statistical Manual of Mental Disorders, Third Edition (DSM-III) (American Psychiatric Association 1980) were heavily influenced by psychoanalytic theory. Diagnostic and Statistical Manual of Mental Disorders, First Edition (DSM-I) (American Psychiatric Association 1952) included various anxiety states under “psychoneurotic disorders” and assumed that they were reactions to unconscious emotional conflict, with or without external provocation. In particular, in DSM-I, the disorders that were considered to be anxiety-related included “anxiety reaction,” “phobic reaction,” and “obsessive-compulsive reaction.” In addition, normal personalities exposed to catastrophic trauma could suffer “reversible decompensations” that were labeled “gross stress reactions,” a forerunner of what is now considered PTSD. The consideration of anxiety disorders in Diagnostic and Statistical Manual of Mental Disorders, Second Edition (DSM-II) (American Psychiatric Association 1968) did not significantly differ from DSM-I. This early stage, the development of diagnostic categories, reflected the broader challenge of dissociating between state (reactive) and trait (neurosis) conditions of anxiety. In the 1950s, 1960s and 1970s, several nonpsychoanalytic approaches began to suggest subdivisions of categories considered in DSM-I and DSM-II. In Britain, the behavior therapist Isaac Marks examined phenomenology, family history, and psychophysiology in his clinical population and subdivided phobic disorders, into agoraphobia, social phobia, and specific phobias (Marks and Gelder 1966). In the US, psychiatrist Donald Klein and colleagues found that patients with unexpected panic attacks often went on to develop a fear of having further panics (anticipatory anxiety) and a fear of traveling places where help was hard to obtain or rapid exit was difficult (e.g., agoraphobia) (Klein and Fink 1962). Klein distinguished this syndrome, which he called PD with or without agoraphobia, from more chronic, but less intense anxiety (which ultimately became generalized anxiety disorder (GAD)) on the basis of phenomenology, course of illness, and response to pharmacologic treatment. These advances reflected an initial improvement in diagnosis on the basis of more sophisticated clinical and pharmacological phenotyping.

These findings culminated in the DSM-III (American Psychiatric Association 1980) classification of anxiety, which fundamentally altered psychiatric nosology from an etiological one (based largely on psychoanalytic theory) to a set of descriptive categorical diagnoses (Mayes and Horowitz 2005). DSM-III contained for the first time an umbrella category of anxiety disorders and operational criteria for distinct anxiety disorders within it. The umbrella category had two main components: the phobic and the anxiety disorders (“neuroses”). The phobic disorders consisted of agoraphobia with or without panic attacks, social phobia and simple phobia. Agoraphobia was characterized as manifesting marked fear and avoidance of being alone or in public places from which escape might be difficult. This formulation is close to our current view. Social phobia, however, was narrowed from Marks’ conception of fear and avoidance of performance or social situations to a conceptualization limited largely to performance anxiety, while more generalized interpersonal fear and avoidance was called avoidant personality disorder. The term simple phobia was reserved for persistent, irrational fears and avoidances of objects or situations that did not fit agoraphobia or social phobia.

In DSM-III, the anxiety states included PD, GAD, obsessive-compulsive disorder (OCD), and PTSD. The distinction between PD, characterized by unexpected, paroxysmal panic attacks, and more persistent but less intense emotional and physical anxiety symptoms of GAD, was initially spurred by Klein’s pharmacological dissection of anxiety disorder. The distinction proved clinically significant and robust. It was therefore carried forward into Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R) (American Psychiatric Association 1987) and DSM-IV (American Psychiatric Association 1994) (see below), although recently there is evidence that GAD bears a closer relationship to major depression than to the anxiety disorders (Kendler et al. 2007). OCD, while recognized in earlier classifications, was given operational criteria for the first time. PTSD, foreshadowed by DSM-I’s “gross stress reaction,” was officially recognized and given operational criteria that included a “recognizable stressor that would evoke significant symptoms of distress in almost everyone” and features of avoidance and reexperiencing of the traumatic situation along with symptoms of hyperarousal and emotional numbing.

DSM-III-R’s (American Psychiatric Association 1987) dissection of the anxiety disorders was not a major departure from DSM-III, but there were some notable changes. Widespread fear and avoidance of many interpersonal situations was recognized for the first time as an anxiety disorder, and included in social phobia together with the specifier “generalized type.” In DSM-III, social phobia was limited to performance anxiety, and the more generalized interpersonal fears and avoidance were considered a manifestation of avoidant personality disorder. This change was important, because
research beginning in the late 1980s demonstrated that generalized social phobic symptoms were amenable to pharmacological (Liebowitz et al. 1992) and cognitive behavioral (Heimberg et al. 1990) treatments, which were less likely to be considered if practitioners thought affected patients were suffering from personality disorders. This success in treatment derived from research on the psychobiological basis of anxiety (see below). Other changes in DSM-III-R were the elevation of worry and apprehensive expectation from one of several possible symptoms of GAD to its defining feature, and increasing the minimum required duration for diagnosing that disorder from one to six months.

Clinical Picture
The principal anxiety disorders included in DSM-IV are as follows: PD with or without Agoraphobia, Agoraphobia without history of PD, GAD, OCD, PTSD, Acute Stress Disorder, Social Anxiety Disorder (SAD) (Social Phobia), and the Specific Phobias. The major changes from DSM-III-R were dropping the terms anxiety and phobic neurosis, completing the nosology’s transformation from a theoretical to a symptomatic base, and adding the condition of acute stress disorder for immediate overwhelming reactions to catastrophic trauma. Below, we briefly consider each of these anxiety disorders in terms of phenomenology, course of illness, prevalence, morbidity, comorbidity, and differential diagnosis.

Panic Disorder and Agoraphobia
The key feature of PD is the recurrence of unexpected panic attacks. These episodes of severe anxiety seem unprecipitated, rise in intensity in seconds to minutes, and reach a crescendo marked by physical and emotional symptoms. These symptoms typically include rapid or pounding heart beat, shortness of breath, lightheadedness, dizziness, nausea and/or paraesthesias, a fear of dying, losing control or going “crazy,” and an urgent desire to flee. Individuals suffering such panic attacks are initially terrified by the experience, and begin to dread the possibility of having recurrences, which takes the form of an anticipatory anxiety. Affected individuals often become fearful and avoidant of going places where neither assistance nor escape are options should an attack occur; agoraphobia is also diagnosed when such an avoidance pattern becomes persistent and is a source of distress or disability.

PD has a usual onset in the late teens or 20s, although some cases begin decades later. The condition can be episodic or chronic. There are no proven precipitants, although endocrine changes like hypothyroidism or sudden separation from trusted figures may be triggering events in vulnerable individuals. Lifetime prevalence of PD with or without agoraphobia is 4.7%, and for agoraphobia without panic, the comparable figure is 1.4% (Kessler et al. 2005). PD can be highly distressing, and individuals who also become agoraphobic can be totally disabled and unable to travel anywhere if not accompanied by a trusted figure. Depression is a common sequela, sometimes with suicidality. Other anxiety disorders and substance abuse disorders are also common comorbid features. Differential diagnosis of PD includes cardiac arrhythmias, pulmonary and gastrointestinal disorders, inner ear disturbance, SAD, specific phobias and generalized anxiety disorder.

Generalized Anxiety Disorder (GAD)
According to DSM-IV the key features of GAD are excessive anxiety and uncontrollable worry over an extended period of time, with six months as a minimum. Associated symptoms include restlessness or feeling keyed up or on edge, being easily fatigued, difficulty concentrating, irritability, muscle tension and disturbed sleep. These symptoms suggest a dysfunctional activation of normal fear circuits. Indeed, the diagnosis is buttressed by results of neuroimaging studies that reveal increased activation of brain regions associated with fear (see below).

GAD tends to be a chronic condition, with waxing and waning symptoms dependent in part on current life circumstances. The lifetime prevalence rate for adults is 5.7% (Kessler et al. 2005). GAD can be disabling at times, but more often it interferes with a person’s quality of life by reducing the ability to relax, be productive or optimistic. It is a risk factor for both affective and substance abuse disorders.

GAD is highly comorbid with other anxiety disorders, as well as major depressive disorder. In fact, GAD is a risk factor for major depressive episodes and appears to share a common genetic basis (see below). GAD patients are stressed by normal life conditions and lack more active coping skills, perhaps exacerbating the effect of stress on mood. The strong link between GAD and affective disorder may result in the shift of GAD into the affective disorders in DSM-V. Differential diagnosis of GAD includes depressive disorder, PD, OCD, dependence on sedative medication and substance abuse disorders.

OCD
OCD is characterized by obsessions, which are repetitive intrusive thoughts that are highly anxiety-provoking, and compulsions, which are either mental or behavioral rituals or avoidances intended to alleviate the distress caused by the obsessions. Interestingly, animal studies suggest that such “displacement” behaviors actually do reduce hormonal indices of distress. The rituals of OCD are often normal behaviors, and thus a critical feature is the degree to which the rituals become excessive and interfere with normal function. Obsessions can take a variety of forms and shape the compulsive response. Unwanted thoughts about dirt, germs or contamination often lead to compulsive and extensive washing and bathing. Repetitive thoughts about whether a task was properly performed (locking the door, shutting off the stove or an electrical appliance) can lead to compulsive checking behavior. Intrusive thoughts about hurting oneself or others are usually associated with mental rituals that are aimed at neutralizing horrific images. Persistent doubting and uncertainty about whether something will be needed in the future makes it very hard to throw things away, leading to compulsive hoarding.

OCD can be crippling, making it hard to learn, hold a job or perform normal household tasks. It can arise in childhood, adolescence or young adulthood, and assume either an intermittent or chronic course. Lifetime prevalence appears to be 1.6% (Kessler et al. 2005). Because of morbidity and chronicity, OCD ranks high on the World Health Organization’s list as a contributor to the overall burden of illness. OCD is also highly comorbid with depression, tic disorders and other anxiety disorders. Differential diagnosis for OCD...
includes tic disorders, GAD, depression with ruminations, specific illness phobias, and schizophrenia.

**Post Traumatic Stress Disorder and Acute Stress Disorder**

PTSD describes the severe emotional disturbance that follows exposure to a life-threatening or terrifying experience. The features of PTSD include elements of reexperiencing the traumatic event, avoiding conditions reminiscent of the trauma, a general numbing of emotional responsiveness, and symptoms of increased arousal. Reexperiencing can take the form of nightmares about the traumatic event, having frequent, unusually vivid, disturbing recollections, or flashbacks, that may include recurrent sensations as though the traumatic event was reoccurring. Trauma-related avoidance involves conscious suppression of thinking or talking about the event, avoiding reminders of the event, and the inability to recall aspects of the trauma. Emotional numbness can be manifest as a loss of interest in formerly meaningful life activities, feelings of detachment and estrangement from other people, a restricted range of affect, and pessimism about being able to achieve a normal life. Thus, chronic PTSD is often comorbid with depression. Increased arousal is apparent in symptoms of insomnia, irritability, difficulty concentrating, hypervigilance and increased startle response.

Current diagnosis of PTSD is linked to the occurrence of trauma. However, the distinction between acute and chronic PTSD is clinically important. PTSD symptoms immediately after severe trauma are common, but their prevalence diminishes with time. For example, over 90% of rape victims express acute PTSD one week after the event, whereas far fewer, about 40–50% of victims, still express a full PTSD state by 6–12 months later. Likewise, the frequency of PTSD symptoms declined in the victims of the 9/11 attacks. PTSD symptoms appear to abate as the victim begins to place the event into a specific spatial-temporal context, and becomes less affected by unprovoked recall, avoidance, and hypervigilance. The most relevant clinical state is chronic PTSD in which there is no decline in the frequency or severity of the PTSD symptoms. Thus, the clinical literature in PTSD has come to emphasize individual differences in vulnerability for PTSD (Brewin et al. 2000) and the process of recovery from trauma. Factors that predict recovery from acute PTSD include the magnitude of the initial reaction to the trauma, the current level of social support, persisting adversity, and the quality of early family life (see below).

PTSD has a lifetime prevalence of 6.8% (Kessler et al. 2005) and can follow a variety of terrible experiences such as physical or sexual abuse in childhood, rape, or armed robbery, exposure to violent combat in military service, or the experience of imprisonment and torture. Chronic PTSD is highly disabling and often leads to depression and substance abuse. Issues that sometimes complicate the diagnosis of PTSD are whether the stressor meets the necessary threshold, and the possibility of malingering in situations where compensation or benefit issues are involved.

Because PTSD, as defined by DSM-IV, requires that symptoms be present for at least a month, another category was needed for individuals who become highly symptomatic immediately after exposure to a severe trauma. Symptomatically, the criteria are similar to PTSD except that dissociative symptoms are more prominent. The differential diagnosis includes brief psychotic reactions, substance induced disorders and malingering. The condition is what Freud described as “traumatic neurosis.”

**SAD (Social Phobia)**

SAD is characterized by fear of social or performance situations in which a person is exposed to scrutiny by others, and dreads appearing foolish or inept. It is common, with a lifetime prevalence of 5–12% depending on the sensitivity of the criteria applied to the data (Kessler et al. 2005, Grant et al. 2005, Narrows et al. 2002). Most affected individuals avoid feared situations, but some endure with a high degree of distress. If the fear and avoidance involve only performance situations (public speaking, interviewing, artistic performances), the individual expresses a non-generalized form of the disorder. If the fears extend to common interpersonal situations such as meeting unfamiliar people, going to parties, talking with colleagues, etc, then the generalized form is diagnosed. For clinicians, SAD may be difficult to recognize, as it appears to represent the tail end of a normal distribution for some underlying trait, such as shyness or inhibition. This is especially true for children that commonly express increased fearfulness. SAD is commonly associated with a heightened response to evaluative social situations as well as to social displays of emotion.

SAD begins early; the generalized form is often manifested in the high school years. While the non-generalized form can be disabling in particular instances, the generalized form is often so, interfering extensively with school, work and social life. Depression, substance abuse (particularly alcohol) disorders and other anxiety disorders are frequently comorbid, however, SAD usually begins first and may directly contribute to the comorbid conditions. Differential diagnosis includes schizoid personality disorder, agoraphobia, and chronic depressive conditions and shyness as a trait on the normal spectrum, which lack the distress and impairment of SAD. In the current nomenclature, avoidant personality disorder largely overlaps with the more severe form of SAD.

**Specific Phobia**

Phobias involve marked and persistent fear that is excessive or unreasonable, cued by exposure to specific stimuli that usually and reliably provokes an immediate anxiety response. DSM-IV distinguishes animal, natural environment (heights, storms), blood-injection-injury, situational (enclosed places, elevators, airplanes) and other types based on the focus of fear. Specific phobias are usually more distressing than disabling, have a high lifetime prevalence of 12.5% (Kessler et al. 2005), can have an early age of onset, and are usually chronic. Other anxiety disorders may be comorbid. Differential diagnosis includes agoraphobia and SAD, PTSD, OCD and hypochondriasis.

**Genetic Contributions to Anxiety Disorders**

Estimates of heritability, that is, the proportion of risk contributed by genetic variation (including gene–environment interactions) are commonly derived from studies with monozygotic and dizygotic twins that share 100 and 50% of their genes, respectively. Heritability estimates for anxiety disorders range from 20–50% depending on disorder and
study. Four of five studies, including two large epidemiologically based samples found greater concordance for PDs in monozygotic versus dizygotic twin pairs (Kendler et al. 2001, Skre et al. 1993, Scherrer et al. 2000, Torpersen et al. 2000, Andrews et al. 1990). A recent meta-analysis of the subset of these data that met strict methodologic criteria (3 twin, 5 family interview studies) estimated heritability of PD at approximately 48% (Hettema et al. 2001). Several twin studies reported moderate genetic heritability of a variety of irrational fears that are frequently the subject of social and specific phobias (Rose and Ditto 1983, Torpersen 1979). The only population based twin study of DSM-phobic disorders obtained moderate heritabilities for social phobia (51%) and three subtypes of specific phobia: animal (47%), situational (46%) and blood injury (59%) (Kendler et al. 1999, Hettema et al. 2005). A series of analyses in two population-based twin samples indicate a modest genetic contribution (heritability 15%–30%) to risk for GAD (Kendler et al. 2006, Scherrer et al. 2000, Kendler 1996). Direct interview family studies indicate significantly elevated risk for GAD among first degree relatives of individuals with GAD (Noyes et al. 1987, Mendlewicz et al. 1993). Thus, there is considerable evidence for familial transmission of anxiety disorders that likely reflects a genetic predisposition.

Linkage and association studies can indicate respectively the involvement of a particular genomic region or allelic variant. Though there are some promising leads, specific liability genes have not been identified. The aggregation of these disorders in families is “complex” and does not follow typical Mendelian patterns (e.g., dominant, recessive). It seems likely that in addition to a large non-genetic contribution the heritable mechanisms that predispose to anxiety disorders will involve multiple genes as well as considerable heterogeneity within each DSM category. Of course genes encode for proteins, not disorders and thus there is a continuing discussion as to what is inherited: risk for a particular disorder, a general anxiety proneness that is shaped into a particular syndrome by subsequent environmental events or some combination of both scenarios. More recently it has been speculated that genetically based variation in certain neural circuits and their function (e.g., associational fear learning and extinction, memory consolidation; autonomic tone) may underlie a predisposition for anxiety disorders. Thus, studies have employed a candidate gene approach based on working models of the neurobiology of anxiety. Despite the apparent merits of this approach, the only well-replicated finding is the Val158Met polymorphism of the catechol-O-methyltransferase (COMT) gene on chromosome 22q. COMT catalyzes the degradation of dopamine in the prefrontal cortex, and the function of this region is critical across multiple anxiety disorders. Four studies (Hamilton et al. 2002, Woo et al. 2002, Domschke et al. 2004 and Rothe et al. 2006) report significant associations between PD and a COMT Val158Met polymorphism. It is not known if these associations reflect an involvement of COMT or another nearby gene that confers risk for PD. There are negative candidate gene studies attempting to link social anxiety to genes in the serotonin and dopamine systems (Stein et al. 1998, Kennedy et al. 2001). A recent small study (N = 32) of generalized social phobia patients found an association between serotonin transporter (5HTTLPR) genotype and social anxiety (Stein et al. 2006).

Research on the genetic basis of vulnerability for anxiety disorders is hampered by the overlap in diagnostic categories. One approach to this problem is that of a dimensional approach that emphasizes specific endophenotypes rather than diagnostic categories. This approach is buttressed by the findings from twin studies that relevant endophenotypes (e.g., fear conditioning, startle response) show different patterns of heritability (Siever et al. 2002). These direct measures of function are more likely to have specific neurobiological substrates that more clearly associate with specific genomic variants than do broader diagnostic categories that reflect multiple component processes. Thus, the future success of studies on the genetics of anxiety disorders will benefit from an improved knowledge of the neurobiology of relevant psychological and physiological processes that are emerging from studies of animal models.

**Animal Models of Anxiety**

**Fear and Anxiety in Humans and Animals**

In spite of their value, animal models of psychiatric conditions are limited by differences in the brains of humans and other animals that give rise to differences in mental and behavioral functions (Kalenuik and Tuohimaa 2004). Humans’ use of language and imagination to conceptualize and anticipate threats, even highly improbable or physically impossible threats, cannot be fully modeled in animals. It is therefore important to be clear about which components of human anxiety, or the vulnerability to anxiety, can be suitably studied using animal models. Fear and the cognitive processes that regulate the emotional state of fear are normal responses to threat or actual danger. In all animals, these events activate the brain’s fear system, coordinating physiological adaptive responses that include behavioral responses (flight, flight, and self-protective immobility or freezing) and changes in autonomic and endocrine activity necessary to provide increased metabolic support. When the threat is posed by an immediately present or imminent stimulus, the emotional response of the organism is typically called a state of fear. When the activation of the fear system in the brain occurs in response to cognitive processes evoked by a perceived threat is not present or imminent, either because it is poorly defined or temporally remote (in the future), the emotional state is usually called anxiety. Thus, fear is a sensory-driven reaction of the fear system to threat, while anxiety occurs when the fear system is activated by cognitive processes that predict and appraise possible threats. The importance of this distinction is apparent in the various clinical states of anxiety, each of which is characterized by an enhanced apprehension of threat resulting in the activation of the fear system. However, anxiety disorders are characterized by cognitive processes that evoke a maladaptive level of activity within the fear system. In general, it is now believed that the source of the disorder lies within the cognitive processes and not within the fear system itself. Thus, as described in the section on the pathophysiology of anxiety disorders below, the critical brain regions that underlie anxiety disorders lie not within the neural structures directly responsible for the expression of fear, but rather in those regions that regulate the activity of the fear system, including in the prefrontal cortex, the amygdala and the hippocampus. Thus, anxiety disorders
reflect cognitive-perceptual dysfunction; the severity of the disorder is defined by the degree to which fear responses are activated. This is true even for PTSD, which is caused by a clearly defined traumatic event, but the symptoms of which are manifestations of fear such as hypervigilance, enhanced startle, and avoidance that are activated by anticipation of a reoccurrence of the event. The fear system is activated by cognitive states that are direct reminders of the trauma (such as happens during during flashbacks and nightmares). GAD, characterized by a lower level of chronic activity in the fear system, is defined by the cognitive state of worrying about hypothetical or imagined situations and consequences. In each case, the overt symptoms of the anxiety disorder is manifested by, and its severity determined by, the maladaptive activation of the fear system. But the origin of the disorder lies in the neural structures that regulate the activity of the fear system. Thus, as discussed in the next sections, patients with anxiety disorders as well as those with an increased vulnerability for anxiety disorders exhibit an attentional bias towards threat.

People in states of fear often have conscious experiences, or feelings, that seem to define the state. However, as William James pointed out (James 1884), conscious feelings are often the outcomes of; rather than the essence of, underlying emotions. All animals, including simple single cell organisms, detect and respond to danger in ways that enhance survival, regardless of whether they consciously experience fear and anxiety (LeDoux 1996, 2000, Hofer 1992). Moreover, such responses can be conditioned, such that the probability or magnitude of the response reflects an anticipatory state. Such conditioned fear responses occur in drosophila and are therefore a phylogenetically well-conserved response to danger. Studies demonstrate that fear arousing stimuli can be presented to people in such a way as to elude conscious perception, but nevertheless engage the brain’s fear system and elicit autonomic nervous system (ANS) responses (e.g., Ohman and Mineka 2001, Etkin et al. 2005a). These findings reveal that the fear system can be activated independent of conscious awareness, which therefore can be considered as distinct from the neural systems that underlay the cognitive regulation of the fear system.

The expression of fear involves similar circuits in humans and other mammals, including those that detect threat and regulate fear in the presence of threats (LeDoux 1996, 2000, Maren and Quirk 2004, Phelps and LeDoux 2005, Phelps 2004, Sotres-Bayon et al. 2004, Quirk and Beer 2006). Thus, in humans and rodents, the amygdala plays a key role in processing sensory cues associated with threat, while the medial prefrontal cortex (mPFC) is pivotal for the regulatory higher-order cognitive processes. The hippocampus is likely involved in processing spatial and temporal information essential for contextual learning about potential danger. Neuroimaging studies reveal clear evidence for dysfunction within all three neural systems in various forms of anxiety disorders (Dougherty et al. 2004, Liberzon and Martis 2006).

There are limitations to animal models. While the expression of fear responses is very similar in humans, primates and rodents, greater evidence for species differences emerge as we consider the cognitive processes that regulate the activation of the fear system. For example, while the rat shows a highly functional medial prefrontal system, this region is substantially more complex in humans. Nevertheless, whereas fear and the regulation of fear responses in humans reflect their unique cognitive functions, the fundamental networks that process threats and initiate states of fear are similar in rodents. Thus, the discussion of animal models of fear and anxiety refers not to their subjective aspects, but to behavioral and/or physiological responses controlled by evolutionarily conserved networks that function unconsciously as well as to the cognitive processes that regulate the fear system. Studies with animal models that focus on the latter are those with the greatest relevance to anxiety disorders in humans.

**Animal Models of Fear, Anxiety, and Fear Conditioning**

Perhaps the most common approach to modeling fear and anxiety in animals involves the use of behavioral tasks that elicit unequivocal signs of fear in normal animals. In many instances, the fear responses are directly comparable in humans and other animals. For example, studies with humans and other animals use startle paradigms that examine responses to sudden and potent stimuli (loud noises). These responses are the result of a direct and unconscious activation of the fear system. A startle response in the rat is defined by a motor response, flinching, that can be readily quantified; the louder and more sudden the noise, the greater the flinch. In humans, the same conditions elicit a startle response defined by an eye-blink as well as a flinching. Both responses can be quantified and used as a measure of the activation of the fear system. Likewise, both humans and rats show “fear-potentiated startle” in which the magnitude of the startle response is enhanced by the presentation of threatening stimuli. Thus, a light that was systematically paired with an electric shock presented prior to the loud noise enhances (or potentiates) the magnitude of the startle. This effect is apparent in both humans and rodents. The magnitude of the potentiation (the increase above the baseline startle condition) defines fear-potentiated startle, which can be interpreted as anxiety since it depends on the cognitive processes associated with prior learning about the light. States of apprehension also potentiate the startle response. Thus, in the rat (normally a nocturnal animal that shies away from daytime conditions), a loud noise presented to the animal in a brightly lit room evokes a greater startle response. In humans, conditions that simulate night, such as a dark room, potentiate startle. These conditions represent relevant models for anxiety disorders since both examine the influence of cognitive states that regulate the expression of fear responses.

Additional models of anxiety involve cognitive states, which normally emerge when animals are placed into novel settings, comparable to apprehension and uncertainty. Thus food-deprived animals provided food in a novel setting show a longer latencies to eat compared to animals given food in a familiar setting, a behavior called novelty-induced suppression of feeding; Bodnoff et al. 1989, Dulawa and Hen 2005). The novelty-induced delay in feeding is eliminated by prior treatment with an anxiolytic drug, which has no effect on eating in the familiar setting. Anxiolytic drugs also increase the willingness of rats or mice to explore brightly-lit novel areas. Importantly, while anxiolytic drugs have no effect on the expression of pure startle responses,
they effectively dampen fear- or light/dark-potentiation of a startle response (Davis 2006). This finding provides further pharmacological evidence for the distinction between the fear-system, which is resistant to anxiolytic medications, and the cognitive systems that regulate fear, which are sensitive to such compounds.

Fear or light/dark potentiated startle are seen in normal human subjects that show no evidence of anxiety disorders. Predictably, patients with anxiety disorders show exaggerated physiological responses to threats, such as increased responses of the ANS revealed by fear-potentiated startle responses (Morgan and LeDoux 1995, Roth 2005, Cornwell et al. 2006). Likewise, patients with anxiety disorders also show enhanced Pavlovian fear conditioning, which depends upon cognitive processing of stimuli that predict aversive events. Thus, novelty-induced fear, fear conditioning and potentiated-startle responses are considered here as models of anxiety processes. Animal models of these processes have the important advantage of a direct human equivalent. This has been invaluable in translating the findings from studies with rodents and primates to human clinical research, especially research using neuroimaging approaches (see below).

Since the expression of fear in behavioral models of anxiety is reduced by treatment with anti-anxiety medications (Gray 1982, File 1987, Blanchard et al. 2001), animal models of anxiety are used to screen drugs for their potential efficacy in relieving anxiety. Commonly drugs such as the benzodiazepines (BZs), which alleviate anxiety in humans, are effective in such animal models. Anxiolytic drugs thus reduce overt behavioral measures of fear, such as freezing, and also increase active coping behaviors such as exploration of the threatening stimuli if the danger is not direct and immediate (i.e., exploration and risk assessment). Microinjections of BZs into the amygdala are generally as effective as systemic application, consistent with the amygdala’s central role in anxiety. The conflict tests, which create a conflict between a fear-evoking condition and a motivation to obtain a reward, are especially useful in the testing of novel anxiolytic agents (File 1987, McCown et al. 1983, Millan and Brocco 2003, Quintero et al. 1985). Anxiolytic drugs such as BZs and alcohol reduce anxiety in animal models and reduce situational anxiety in healthy people as well as in those with debilitating chronic anxiety.

Animal behavioral models have been the most direct means for exploring the neural circuits of fear and, importantly, for clinical translational studies of the cognitive processes that regulate the fear system, which are altered in anxiety disorders (Rosen and Schulkin 1998, Hariri et al. 2005, 2006, Cahill et al. 1999, LeDoux 1996, 2000). Pavlovian fear conditioning has been especially useful in characterizing the fear system at the level of circuits, cells and synapses, molecules and genes (LeDoux 2000, Rodrigues et al. 2004, Maren and Quirk 2004, Davis 2006). In fear conditioning, a neutral stimulus, the conditioned stimulus, such as a light or tone, is paired with an aversive unconditioned stimulus, such as a shock or loud noise. Through this process of association of the two stimuli, the conditioned stimulus comes to elicit aversive responses formerly elicited only with the unconditioned stimulus. Neural structures involved in fear conditioning converge within the amygdala (Fanselow and LeDoux 1999, LeDoux 2000). Behavioral processes by which organisms learn relationships between specific sensory signals (i.e., cued fear-conditioning) and contexts (i.e., contextual fear-conditioning) that predict danger engage multiple regions of the the amygdala as well as the bed nucleus of the stria terminalis, an extension of the amygdala, the prefrontal cortex, and the hippocampus. Fear responses are regulated through outputs from the central nucleus of the amygdala (Davis 1998).

Efferents of the central nucleus of the amygdala and the bed nucleus of the stria terminalis include the parabrachial nucleus, producing an increase in respiratory rate, the lateral nucleus of the hypothalamus and midbrain sites that activate the sympathetic nervous system causing autonomic arousal and sympathetic discharge, and the reticular pontine nuclei that activate a startle response (Davis 1998, LeDoux 2000). Projections from the central nucleus of the amygdala to the periaqueductal gray region contribute to selected defensive behaviors such as freezing. The central nucleus of the amygdala is also a source of neuronal projections that release corticotrophin-releasing factor (CRF) and activate the noradrenergic neurons of the locus coeruleus (Van Bockstaele et al. 1998), which then influences cortical and hippocampal systems involved in attention and memory regulation. Such CRF effects may involve CRF projections to the bed nucleus of the stria terminalis (Davis 1998), which shows high expression of the relevant CRF1 receptor. Increases in amygdala CRF and noradrenergic activity stimulate the release of CRF from the hypothalamic-paraventricular nucleus and thus activate the hypothalamic-pituitary–adrenal (HPA), or stress, axis (Gray and Bingham 1996). There is a compelling similarity between the downstream consequences of activation of the central nucleus of the amygdala/bed nucleus of the stria terminalis and the symptoms of anxiety disorders (Gorman et al. 2000). There is also evidence for relevant “bottom-up” effects. Thus, the output of these systems, including adrenal glucocorticoids as well as catecholamines of both central and peripheral origin, act on the amygdala to facilitate the recall of information associated with aversive events (Cahill and McGaugh 1998). The dynamic effects of catecholamines on reconsolidation of fear memories via β-adrenergoreceptors in the amygdala (Debiec and LeDoux 2006) have spurred trials of β-blockers following trauma to prevent PTSD (Pitman and Delahanty 2005). Other means of disrupting consolidation or reconsolidation of trauma-based memories (Nader et al. 2000), such as glucocorticoid receptor inactivation during retrieval (Tronel and Alberini 2007), could lead to additional approaches to the prevention of PTSD in the future.

**Extinction and Safety Conditioning are Distinct Forms of Learning**

Fear-conditioning represents a process whereby the individual’s knowledge of the environment regulates the expression of an emotional state. In the case of cued fear-conditioning, this “knowledge” is derived from the learning that results from the pairing of the cue with an aversive event. Stimuli that reliably predict aversive events elicit a conditioned fear response that depends upon the activation of the lateral, basolateral and central nuclei of the amygdala and/or the bed nucleus of the stria terminalis. However, such conditioned fear responses diminish if the conditioned stimulus is no longer reliably followed by the aversive stimulus, a process called extinction. Extinction is an independent form of...
learning (Rescorla and背 1975, Bouton and King 1983, Quirk et al. 2000), not simply the passive waning of a conditioned fear response or an erosion of the fear memory. Rather, it is an active inhibition of the response through subsequent acquisition of information concerning the conditioned stimulus (Bouton and Bolles 1979, Konorski 1967, Pavlov 1927). Extinction learning depends upon projections from the medial prefrontal cortex, notably the infralimbic cortex, to a population of inhibitory GABAergic neurons that inhibit the central nucleus of the amygdala (Morgan et al. 1993, Quirk et al. 2000, Rosenkranz et al. 2003). Thus, Quirk et al. (2003) found that stimulation within this region of the mPFC inhibits the activation of the central nucleus of the amygdala.

Interestingly, classic anxiolytics, such as the BZs, are amnestic agents that therefore block extinction learning (Bouton et al. 1990). These medications also reduce the efficacy of exposure therapy, underscoring that fact that extinction represents a form of new learning. Neuroscience research reveals that the neurotransmitter glutamate acting at the N-methyl-D-aspartate (NMDA) receptor is critically involved in multiple forms learning and memory (Bear 1996, Castellano et al. 2001, Morris et al. 1990, Newcomer and Krystal 2001). Blockade of the NMDA receptor with selective antagonists blocks extinction (Falls et al. 1992). Likewise, compounds that enhance NMDA receptor signaling increase the efficacy of extinction training in rats. One such compound is D-cycloserine does not bind to the NMDA receptor itself, but to the glycine receptor that positively regulates NMDA receptor activity. Preliminary studies with D-cycloserine in humans reveal a significantly enhanced effect of exposure therapy with anxiolytics (Davis et al. 2006).

The induction of anxiety increases amygdala activity in healthy human volunteers (Phelps et al. 2001) and amygdala activity is seen in patients with a variety of anxiety disorders (Stein et al. 2002, Shin et al. 2005, Straube et al. 2005, Protopopescu et al. 2005). Predictably, studies using a variety of fear-inducing conditions reveal strong evidence for increased amygdala activation in patients with anxiety disorders (see Pathophysiology of Anxiety below). These studies also show evidence for the importance of structures like the hippocampus and prefrontal cortex that regulate activity within the amygdala and bed nucleus of the stria terminalis.

Animals respond not only to new information concerning previously threatening stimuli, but also about environmental signals that predict that absence of threat; signals of safety. Safety signals are established in a novel context through repeated and explicit pairing of a conditioned stimulus with the absence of an aversive event. The aversive event occurs randomly when the conditioned stimulus is absent; thus the conditioned stimulus reliably predicts a respite from an otherwise menacing set of conditions. As animals learn safety signals their presentation is associated with decreased activity in the lateral nucleus of the amygdala (Rogan et al. 2005). The inhibition of amygdaloid activity appears in response to signals from the striatum and is thus distinct from extinction learning.

Extinction and safety conditioning form the basis for psychotherapeutic approaches to selected forms of anxiety. For example, phobias are commonly treated with “exposure therapy” that pairs the threatening stimulus with the absence of an aversive outcome. Likewise, an important psychotherapeutic approach in the treatment of PTSD involves the distinction between stimuli that predict a recurrence of the traumatic event from those that do not. Each of these approaches appears to involve brain regions that actively inhibit various regions of the amygdala and might be considered as a fundamental form of emotional regulation.

Animal Models of Anxiety Disorders

The behavioral models described above subject animals to environmental conditions that reliably cause fear or anxiety. However, in humans anxiety disorders are not determined solely by exposure to aversive environmental conditions. For example, only a proportion of people exposed to a severe trauma will develop chronic PTSD, and chronic stress is a risk factor for affective disorders. Animal models are helping to account for individual differences in susceptibility and resilience to stress (Charney 2004), and have the potential to define causal relations between genomic variants or programmed environmental variations and risk of illness. Relevant behavioral manipulations in adult animals typically involve the induction of intense and/or chronic stress (Miller and McEwen 2006, Cohen and Zohar 2004), including immobilization, restraint, electric shock, and cold stress, as well as underwater trauma and predator exposure (Adamec et al. 2006, Korte and De Boer 2003, Morilak et al. 2005, Rau et al. 2005, Rittenhouse et al. 1992, Richter-Levin 1998, Cohen et al. 2004). Importantly, chronic stress alters subsequent performance on an anxiety test (elevated plus-maze) and produces hypertrophy of dendrites in the amygdala. The behavioral effects of chronic stress are usually blocked by concurrent treatment with an antidepressant drug. Chronic stress (or sustained treatment with glucocorticoids) also blocks synaptic plasticity in the hippocampus and produces dendritic atrophy in the mPFC (McEwen 1999, 2007). These effects are potentially associated with enhanced threat-induced activity in the amygdala, and, as described below (see Pathophysiology of anxiety disorders), hippocampal/mPFC dysfunction in humans, which is associated with increased vulnerability for anxiety disorders. Thus chronic stress might enhance the risk for anxiety through effects on the morphology of the neural circuit that regulates fear and anxiety.

The distinction between state and trait fear or anxiety is also important for animal models (Andreatini and Bacellar 2000, Lister 1990). State fear or anxiety is a transient condition elicited by a stimulus or situation. Trait fear/anxiety is an enduring condition that is independent of specific stimuli or contexts. When anxiety is measured in a behavioral task, does that task assess a state or a trait? That some models, especially in normal animals with limited genetic variability, assess state rather than trait anxiety is suggested by the relatively poor test-retest reliability of the elevated plus-maze test, a task widely interpreted as an anxiety equivalent (Andreatini and Bacellar 2000). Behavioral models with rodents that incorporate relevant genomic variations are an important advance in overcoming this limitation. A number of genetic manipulations have been used to create lines of anxious animals. This has been done with selective breeding to enhance performance on anxiety tests (Aguilar et al. 2004, Escorihuela et al. 1997, 1999, Ferre et al. 1995, Pisu and Osinski 2000, Walker et al. 1989, Steimer and Driscoll...
Bearing a selective knockout of the 5-HT \(_{1A}\) receptor or of CRF1 receptors in the amygdala. Animals show greatly reduced levels of anxiety-like behavior in a number of behavioral tests (Smith et al. 1998). The expression of fear in rodents is inhibited by serotonin receptor including at the BZ site. These findings have led to a focus of investigation on the \(\alpha\) and \(\gamma\) subunits that form the BZ receptor. Point mutations in either subunit are sufficient to eliminate BZ receptor binding, and animals bearing a null mutation of the \(\gamma\) subunit show a loss of BZ binding (Gunther et al. 1995) and increased fear-conditioned freezing as well as elevated reactivity to natural aversive stimuli (Crestani et al. 1999).

Although exaggerated symptoms of fear and anxiety are central to all anxiety disorders, each has unique features. Some of the models described above have been targeted for specific disorders. For example, chronic stress, inescapable footshock, and underwater submersion have been used to mimic traumatic stress conditions, such as PTSD (Richter-Levin 1998, Adamec et al. 2004, Cohen et al. 2004, Matar et al. 2006, Pitman and Delhanty 2005, Servatius et al. 1995, Wakizono et al. 2007). PD has been modeled by treating animals with drugs that induce panic in human subjects, such as lactate (Shekhar et al. 1996) or doxapram (Sullivan et al. 2003), and then showing enhanced fear or anxiety in behavioral tests such as the open field, elevated plus-maze, a social interaction test, or fear conditioning. Stimulation of brain circuits (amygdala, hypothalamus) by drugs (Frankland et al. 1997, Sajdyk and Shekhar 1997, 2000, Sanders and Shekhar 1995, Sanders et al. 1995, Keim and Shekhar 1996) or electrical stimulation (Rosen et al. 1996, Rosen and Schulkin 1998) has been used to alter control of autonomic and behavioral responses to model PD (Sajdyk et al. 1999, Shekhar et al. 1999, 2003, Graeff et al. 1993). Models of OCD also exist (Korff and Harvey 2006).

### Amygdala Function and the Pathophysiology of Anxiety Disorders

#### Emotional Processing and Amygdala Function

Studies of the association between attention regulation and anxiety reveal that adults with anxiety disorders exhibit enhanced vigilance and increased attention to threat, as evidenced by reaction times to fear-related words or pictures. As in other species, these effects in humans are attributed to activity of a neural circuit comprised of the amygdala, hippocampus and prefrontal cortex. In humans, aversive stimuli activate the amygdala, which mediates immediate responses and learning and memory for these stimuli. Individual differences in trait anxiety predict the response of the amygdala to unconscious processing of threatening stimuli (Etkin et al. 2005a). Neuroimaging studies reveal increased amygdala activity during the acquisition phase of fear conditioning (LaBar et al. 1995, LaBar et al. 1998, Morris et al. 1998), and patients with amygdala damage show profound deficits in fear conditioning (Bechara et al. 1995, LaBar et al. 1998).

In addition, the hippocampus is involved in processing spatial and temporal information related to threats as indicated by so-called “trace conditioning.” In this paradigm, in which the US follows the CS after a delay, the hippocampus, amygdala, and anterior cingulate cortex are recruited. The hippocampus is also critical in associating the threat with the predictive stimuli across temporal intervals. The hippocampus also mediates learning and new learning. Activation of the amygdala is primary and thus individual differences in the degree of amygdaloid activation during fear conditioning predict the strength of a conditioned autonomic fear response (Furmark et al. 1997). Moreover, as in rodent models, hormones released in response to stress (catecholamines and glucocorticoids) facilitate the establishment of emotional memories in humans (Cahill and McGaugh 2003, Wehner et al. 1997, Paterson et al. 2001, Morilak et al. 2005, Brunelli and Hofer 2007) and with transgenic mice (Gross and Hen 2004, Leonardo and Hen 2006, Sible and Hen 2001, Heisler et al. 1998, Tecott et al. 1998, Tecott 2000, Low et al. 2000, Shumyatsky et al. 2005) that alter genes expressed in the brain and then assess performance on anxiety tests. Of course, these studies are also critical in defining relevant genomic targets within the fear/anxiety neural circuitry. In rodents, increased anxiety is associated with the activation of CRF1 receptors in the amygdala and the locus coeruleus that regulate noradrenaline release in corticolimbic regions. Thus, mice carrying a deletion of the gene for the CRF1 receptor show greatly reduced levels of anxiety-like behavior in a number of behavioral tests (Smith et al. 1998). The expression of fear in rodents is inhibited by serotonin activity in the hippocampus and amygdala, an effect that involves GABAergic transmission in the amygdala. Animals bearing a selective knockout of the 5-HT\(_{1A}\) receptor or of selected subunits of the GABA\(_{A}\) receptor show enhanced anxiety (Crestani et al. 2002, Gross et al. 2000).

Studies with animals bearing gene mutations provide a critical test of cause—effect relations between specific neural signals and behavioral phenotypes, and can serve as the basis for human clinical research. For example, studies with humans lend further support to the idea that alterations in the GABA\(_{A}/BZ\) receptor complex might form the basis for individual differences in vulnerability for anxiety disorders. Unmedicated patients with a history of PD show a significant decrease in labeling of the BZ receptor antagonist \([^{11}\text{C}]\text{flumazenil}\) in the orbitofrontal cortex and amygdala/hippocampal region in PET studies (Malizia et al. 1998). The findings are consistent with those of pharmacological measures of reduced BZ receptor sensitivity in patients high in neuroticism (Glue et al. 1995), PD (Roy-Byrne et al. 1990, 1996), or generalized anxiety (Melo de Paula 1977, Ollowitz and Robins 1983). These findings are at least consistent with the idea that decreased BZ binding levels in critical sites, such as the amygdala, are related to increased vulnerability to anxiety disorders (Gorman et al. 2000).

These findings, together with the well-defined anxiolytic effects of BZ agonists, inspired studies on the molecular basis of GABA\(_{A}/BZ\) receptor function in rodents (McKernan and Whiting 1997). Predictably, behavioral responses to stress are inhibited by BZs, which exert their potent anxiolytic effect by enhancing GABA-mediated Cl\(^-\) currents through GABA\(_{A}\) receptors (McKernan and Whiting 1997, Mehta and Ticku 1988). BZ receptor agonists exert anxiolytic effects via their actions at a number of limbic areas, depending upon the test conditions. However, to date the evidence is perhaps strongest for BZ effects at the level of the basolateral complex of the amygdala, comprising the lateral, basal and anterior basal nuclei (Pitkanen et al. 1997), and the central nucleus of the amygdala. Direct administration of BZs into the basolateral or central regions of the amygdala yields an anxiolytic effect. Interestingly, dynamic variations in GABA\(_{A}\) receptor function often occur as a result of allosteric modulation of the GABA\(_{A}\) receptor including at the BZ site. These findings have led to a focus of investigation on the \(\alpha\) and \(\gamma\) subunits that form the BZ receptor. Point mutations in either subunit are sufficient to eliminate BZ receptor binding, and animals bearing a null mutation of the \(\gamma\) subunit show a loss of BZ binding (Gunther et al. 1995) and increased fear-conditioned freezing as well as elevated reactivity to natural aversive stimuli (Crestani et al. 1999).
1998). These effects involve the activation of glucocorticoid and \( \beta \)-adrenergic receptors in the amygdala. Indeed, agents that block these receptor sites are considered promising areas for therapeutic development in clinical cases that involve traumatic memory (Tronel and Alerbini 2007).

Further evidence for the importance of the amygdala in emotional processing of sensory information emerges from studies in human populations with amygdala damage. Amygdala lesions in humans are associated with impairments in the recognition of fear and anger (Scott et al. 1997). Humans with such lesions are more likely than controls to judge photographs of strangers as trustworthy and approachable (Adolphs et al. 1998). Patients with amygdala seizures, involving repeated excess activation of the amygdaloid complex commonly suffer from severe anxiety disorders (Picardi et al. 2007). In rodents, amygdaloid kindling, which replicates the seizure activity of these patients, dramatically increases anxiety (Kalynchuk et al. 2001).

**Pathophysiology of Anxiety Disorders**

Anxious individuals of any age show an attentional bias to threat. Severe threat rivets attention in all people, whereas mildly to moderately threatening conditions are best for distinguishing individuals with increased trait anxiety or overt anxiety disorders (e.g., Grillon et al. 1999). Such conditions evoke highly focused attentional responses in anxious individuals, which are comparable to normal individuals' attentional response to serious threats. Neuroimaging studies, which are among the most powerful techniques for studying brain pathophysiology, reveal this attentional bias, which reflects the altered cognitive–perceptual processing of sensory information through the prefrontal–amygdala circuit. Attentional biases towards threat are associated with cognitive impairments, such as disruptions of working memory that occur as a function of the increased distractability associated with hypervigilance. Such effects are, in part, associated with catecholamine influences on prefrontal function (Birnbaum et al. 1999). Not surprisingly, there is considerable comorbidity between anxiety disorders and attentional-deficit disorder (ADD).

Images of human faces are the most common stimuli used in neuroimaging of human anxiety. Studies among adults suggest that SAD is associated with a heightened response in the amygdala both to complex evaluative social situations and to relatively simple stereotyped facial displays of emotion (Evans et al. 2007). One study also demonstrated enhanced fear conditioning to facial stimuli among adults with SAD, which was reflected in changes in the amygdala.

Several studies reported activation of the amygdala in response to facial expressions of fear or anger compared with neutral faces (Morris et al. 1996, Phillips et al. 1997, Stein et al. 2002) or unpleasant versus neutral pictures (Irwin et al. 1996). Predictably, there is neuroimaging evidence of increased amygdala activity in patients with a wide range of anxiety disorders (e.g., Breiter et al. 1996, Rauch et al. 1996). Social phobics seeing neutral faces show activation of the amygdala comparable to that observed in controls in response to aversive stimuli (Birbaumer et al. 1998). Similarly, children with anxiety disorders have increased amygdala activity compared with controls when viewing fearful versus neutral faces (Pine et al. 2005). Taken together, these studies indicate that the amygdala of anxiety disorder patients is more reactive to mildly aversive stimuli.

**Emotional Regulation: Role for the mPFC**

Neuroimaging studies of PTSD patients that focused on combat-related exposure in veterans with PTSD (Rauch et al. 1996, Liberzon et al. 1999, Bremner et al. 1999) have found increased regional activation with measures of cerebral blood flow in the amygdala and decreased activation of the mPFC in response to trauma-related material versus neutral stimuli. Interestingly, an area that consistently shows “de-activation” is the mPFC area 25, which also shows anatomical alterations in depressed patients (Drevets et al. 1997). Not surprisingly there is considerable comorbidity between PTSD and depression. A script-driven imagery and PET study of Vietnam War veterans with or without PTSD showed rCBF decreases in the medial frontal gyrus for the traumatic versus neutral comparison in the PTSD group (Shin et al. 2004). Activity in the mPFC was inversely correlated with changes in the amygdala, which is consistent with the rodent model showing that the mPFC modulated amygdala activity and dampened fear conditioning. Differential activation of the amygdala in patients with PTSD is not limited to specifically trauma-related material. Thus, PTSD patients show increased amygdala responses to facial expressions of fear or anger (Shin et al. 2005). Importantly the magnitude of the response in the amygdala correlates negatively with activity in the dorsal region of the mPFC. Similarly, there is a negative correlation between activity in the ventral medial prefrontal cortex (vmPFC) and that of the amygdala following presentation of aversive pictures or emotional facial expressions (Ury et al. 2003, Kim et al. 2003).

Such patterns of neural activation also predict the magnitude of cortisol responses to stressors (Davidson 2004), which in turn reflects the magnitude of the perceived severity of the threat. Recall that glucocorticoids act on the amygdala to enhance the memory for the event. The negative correlation between activity in the mPFC and the amygdala also relates to cognitive processes during emotional learning and memory. Fear conditioning is an obvious example of an association that activates a negative emotion, and the ability to appropriately extinguish conditioned emotional responses is critical for affect regulation. Phelps et al. (2004) paired a visual stimulus with a mildly painful wrist shock. During the acquisition phase, activity in the amygdala predicted the magnitude of the conditioned emotional response. In the extinction phase, the visual stimulus was repeatedly presented without the US, which normally results in a suppression of the learned response. Following extinction, activity within the vmPFC predicted the magnitude of the conditioned emotional response. Stimulation of the rodent analog of vmPFC inhibits responses in the amygdala (Quirk et al. 2003, Rosenkranz et al. 2003). Across multiple species the mPFC has direct projections to the amygdala (Carmichael and Price 1995) as well as to the primary source of ascending serotonergic (dorsal raphé nucleus) and noradrenergic (locus coeruleus) projections. Amat et al. (2005) found that inactivation of an area of the mPFC that contains relevant descending projections eliminates the effect of perceived controllability on behavioral and neurochemical responses to stress. In the
rat, as in humans, the ability to actively control a stressor diminishes the adverse effects; uncontrollable stressors produce far more profound impairments on behavior and neural activity. Lesions of the mPFC rendered controllable stressors as potent as uncontrollable stressors, suggesting that the processing of the information related to the detection of controllability relies upon mPFC function, and likely on descending projections from the mPFC. Thus the diminished activation of regions such as the mPFC in patients with anxiety disorders might underlie an impaired capacity for a 'top-down' regulation of emotional states.

**Therapeutic Targets: The Neurobiology of Coping**

Studies of blood flow and metabolism as well as functional magnetic resonance imaging (fMRI) reveal a common pattern of decreased activation of the prefrontal cortex, cingulate gyrus, and increased amygdala activity in patients with mood disorders (Davidson et al. 1999). Thus, amygdaloid dysfunction is associated with both anxiety and depression (Drevets et al. 1997) and negative affect is strongly correlated with amygdaloid activity in positron emission tomography (PET) scans, particularly in the right amygdala (Abercrombie et al. 1998, Michelgard et al. 2007). Thus, PET studies indicate that right amygdala blood flow is increased in PTSD patients (Rauch et al. 1996, Shin et al. 1997). Importantly, the reciprocal dysfunction in the prefrontal cortex and amygdala is at least partially normalized with successful treatment of the mood disorder (Goldapple et al. 2004). Likewise, Furmark et al. (2002) report that both medication (citalopram) and cognitive behavioral therapy reduce the activation of amygdala and hippocampus in anticipation of public speaking in patients with social phobia. The decrease in the activation of the amygdala predicts symptom severity one year later.

The results of neuroimaging studies converge with those examining the psychological processes that render individuals vulnerable for anxiety disorders. Active cognitive appraisal of emotionally disturbing stimuli and the evaluation of the emotional states associated with such events is a coping style that predicts a reduced risk for anxiety, as well as other forms of psychopathology. Appraisal involves the processing of information related to the stimuli as well as a reinterpretation of the accompanying emotional state that appears to reduce the emotional response and physiological arousal (Phan et al. 2004). Ochsner et al. (2002) used aversive pictures to scan subjects with fMRI and instructed them to attend (be aware of feelings elicited by the picture) or reappraise (reinterpret the picture so that it no longer elicits a negative emotional response). Attending alone was associated with increased emotional responses and increased activity in the amygdala, as well as regions of the PFC associated with processing aversive material. Reappraisal of highly negative scenes reduced emotional responses and increased activation of the dorsal and ventral lateral regions of the mPFC. As noted above, these regions are associated with inhibition of amygdala activity and thus vmPFC activation during reappraisal was inversely correlated with activity in the amygdala. Effective reappraisal associates with increased activation in mPFC regions implicated in working memory, cognitive control, and self-monitoring, and with decreased activation of medial orbital frontal cortex and amygdala, regions implicated in emotion processing. Using a similar paradigm, Phan et al. (2005) showed a reduced rate of amygdala activation in subjects instructed to either respond normally or to actively suppress negative responses through reinterpretation of the material and affect. Successful reduction of negative affect was associated with increasing activation of mPFC and with decreasing activity in the nucleus accumbens and the amygdala, as well as with the intensity of negative affect. Likewise, using functional MRI Schaefer et al. (2002) demonstrated that when subjects were instructed to regulate their negative emotion voluntarily, there occurred a reliable bilateral decrease in amygdala activity that was correlated with the increased signal in the vmPFC (Urry et al. 2003).

Cognitive-based psychotherapeutic interventions that are clinically effective in treating a range of anxiety disorders focus on the issue of appraisal and affect regulation. Not surprisingly, these interventions are associated with alterations in the activity of the mPFC (Etkin et al. 2005a, Roffman et al. 2005, Mayberg 2007). Likewise, clinically effective pharmacological therapies target neural structures implicated in states of anxiety, especially the amygdala and its projections to the noradrenergic neurons of the locus coeruleus. Anxiety disorders are commonly associated with increased central and peripheral noradrenergic activity. Acute BZ treatment in the rat or human reduces fear and this effect is associated with BZ action at the level of the amygdala. The anxiolytic effect of the BZs in the rat can be achieved with direct infusion of the BZ into the amygdala and by the suppression of activity in the locus coeruleus. Selective serotonin reuptake inhibitor’s (SSRI) target this same neural circuit. Coplan et al. (1997) showed that after 12 weeks of fluoxetine treatment, patients with panic who responded to treatment showed a decrease in plasma levels of 3-methoxy-4-hydroxyphenylglycol (MHPG), the main metabolite of noradrenaline. This finding suggests that SSRIs decrease noradrenergic activity, and cardiovascular symptoms associated with panic attacks. The 5-HT projection to the locus coeruleus is inhibitory and SSRI treatment in the rat enhances serotonergic inhibition of basal and stimulated firing rates of locus coeruleus neurons (Blier 2001). Stutzmann and LeDoux (1999) showed that 5-HT modulates sensory input at the lateral nucleus of the amygdala, inhibiting excitatory inputs from glutamatergic thalamic and cortical pathways. The effect of 5-HT is mediated by the GABA_A receptor, which is the principal pharmacological target of the BZs. Thus, the findings from clinical research further implicate the mPFC–amygdala connections in anxiety. As discussed above, there is evidence linking reduced GABAergic function in the amygdala to vulnerability for anxiety in humans. These findings suggest that states of increased anxiety are associated with a diminished capacity in mPFC structures that modulate activity in the amygdala and thereby regulate affect. Increased amygdaloid activity may well serve as a common neural substrate for alterations in the assessment of stimulus salience, conditioned emotional responses, and hypervigilance that define anxiety states.

Neuroimaging studies of individuals with affective disorders provide a biological basis for subgrouping patients on measures of neural activity that are proximal to the symptoms (Etkin et al. 2005b). Indeed, many in clinical psychology and psychiatry argue for such a subgrouping on the
basis of symptoms or specific traits rather than categorical approaches. Neuroimaging studies provide a complementary level of clinical analysis of both pathogenesis as well as treatment outcome. Thus, for example, pretreatment levels of activity in the rostral portion of the anterior cingulate predicted the treatment response to venlafaxine in depression (Davidson et al. 2003). There is also evidence that neuroimaging may provide indications for differential treatment (Etkin et al. 2005b). Among OCD patients, pretreatment levels of activity in the orbitofrontal cortex predicted the response to psychotherapy versus pharmacotherapy (Brody et al. 1998). Moreover, complex affective disorders will likely show multiple etiologies even when the presentation of the current symptoms is similar (Etkin et al. 2005b). Etiology matters for treatment outcome. Thus, Nemeroff et al. (2003) showed that patients with major depression and a history of childhood trauma responded significantly better to cognitive psychotherapy than to an antidepressant medication; patients with major depression but no evidence of childhood trauma showed a better response to the medication. Such findings underscore the importance of etiology and a clear understanding of the intermediate phenotypes, including patterns of neural activity that define the premorbid vulnerability for anxiety disorders.

Vulnerability for Anxiety Disorders

The question of vulnerability lies at the heart of research on anxiety disorders (Yehuda 2004). Surprisingly, not all humans subjected to even profound trauma develop PTSD (Ressnick et al. 1993, Shalev and Freedman 2005, Storr et al. 2007). A critical question concerns the traits that characterize individuals vulnerable for anxiety disorders, and the identity of the critical neural processes that define the high-risk state. Much of the initial clinical research compared patterns of neural morphology or patterns of activation in patient samples and controls. A limitation of such studies is the inability to directly relate alterations in neural activity to the onset of pathology. One example lies in the consistent finding that PTSD associates with decreased hippocampal volume (Bremner 2002). This relation is potentially critical for recovery from PTSD, since the hippocampus is crucial for contextual information. A major challenge following trauma is for the individual to place the event into an appropriate time and place such that memory for it and concomitant emotional responses are limited to situations that realistically predict repeated occurrence of the trauma. Hippocampal dysfunction could thus serve to impair recovery in PTSD. Moreover, hippocampal impairments could serve as a risk for chronic PTSD. However, the dilemma lies in the interpretation of correlational findings that relate hippocampal volume and PTSD. Do such findings suggest that decreased hippocampal volume might render individuals vulnerable for chronic PTSD, or does the chronic PTSD state result in decreased hippocampal volume (Sapolsky 1996), Gilbertson et al. (2002) directly addressed this issue and found that in PTSD subsequent to combat exposure was associated with reduced hippocampal volume by comparison to combat-exposed individuals without PTSD. However, the twins of these subjects, who never experienced combat, showed the same differences in hippocampal volume, suggesting that the differences in hippocampal volume are of developmental origin and define a state of increased vulnerability. A critical question concerns the nature of such an increased state of vulnerability for anxiety.

Studies of functional asymmetries in the mPFC provide a further understanding of the neural basis of emotional regulation and vulnerability for anxiety disorders (Davidson 2004). The processing of stimuli associated with negative emotional states activates regions in the right prefrontal cortex more than on the left. Stimuli associated with positive emotions show the reverse pattern of activation (Davidson et al. 1990, Ahern and Schwartz 1985, Jones and Fox 1992). There are stable, individual differences in baseline prefrontal electroencephalogram (EEG) asymmetries that map onto those observed in emotional reactivity (Davidson 2004). Individuals with a relatively greater prefrontal activity in the right hemisphere show increased shyness, timidity and negative affect (Tomarken et al. 1992, Urry et al. 2004). Individuals with relatively greater prefrontal activity in the left hemisphere show more positive affect, increased sociability and are more likely to approach and explore novel conditions. An attentional bias is revealed in responses to films of positive versus negative content: Left-biased individuals are more responsive to the former, right-biased individuals respond more to the latter. Importantly, these findings suggest that altered activity within the right prefrontal cortex associated not only with increased reactivity to aversive stimuli, but also with negative affect. Both, of course, are cardinal symptoms of anxiety disorders. Such individual differences are apparent in EEG studies with rhesus monkeys. Animals with increased activity in the right prefrontal cortex show elevated levels of CRF in cerebrospinal samples and increased basal cortisol levels (Kalin et al. 1998).

Developmental Origins of Vulnerability for Anxiety Disorders

Behavioral Inhibition

Support for the developmental perspective derives from studies of the longitudinal course and familial nature of anxiety disorders. Familial influences include heritable genetic variants, gene x–environment interactions and environmental effects. Childhood behavioral problems very commonly precede emotional problems in adults. Indeed, many adult anxiety disorders appear to have a childhood or adolescent onset (Kendler et al. 1992, Merikangas 2005) or, in the case of PTSD, predisposing factors stemming from early family life (Udwin et al. 2000). Predictably, research focuses on developmental precursors to endophenotypes that associate with anxiety disorders. Perhaps the most fruitful area is that of research on individual differences in cognitive and affective responses to mild threat in children, subsumed under the term “behavioral inhibition” (Kagan et al. 1987, Pérez-Edgar and Fox 2005). Behavioral inhibition first manifests in infants. It is characterized by increased physiologic reactivity and behavioral withdrawal in response to novelty, including to strangers, inanimate objects, or other forms of challenging situations (Kagan et al. 1987, Fox et al. 2001). Physiological manifestations of behavioral inhibition include low heart rate, variability, accelerated heart rate, increased HPA activity under basal and stimulated conditions, as well as an increased startle response. Among North Americans behaviorally inhibited individuals
comprise the 15% of the population that have the most shyness and timidity. Behavioral inhibition in infancy is a risk factor for anxiety in childhood or adolescence particularly for social phobia or SAD (Biederman et al. 2001).

Behaviorally inhibited infants show high levels of negative emotional states (Pérez-Edgar and Fox 2005), and are typically agitated and fearful in response to novelty. At later ages, behaviorally inhibited children are often wary in social situations and socially withdraw from unfamiliar peers. Maternal ratings of persistent shyness in childhood predict the development of anxiety disorders in adolescence (Prior et al. 2000).

Behaviorally inhibited children are hypervigilant and show an increased startle response, both common characteristics of adults with affective disorders. These children also show heightened fear in response to situations that noninhibited individuals experience as nonthreatening (Pérez-Edgar and Fox 2005). This distinction is comparable to the negative emotional bias that characterizes individuals with increased trait anxiety or with anxiety disorders. Indeed, there are impressive similarities in the defining features of behavioral inhibition and critical features of clinical anxiety (Pérez-Edgar and Fox 2005), including social withdrawal and an avoidant style of coping. Importantly, behavioral inhibition and clinical anxiety are both characterized by an increased attentional bias to threat-related stimuli (Lonigan et al. 2004). For example, when presented with ambiguous situations, young, socially anxious children perceive threat more quickly and report more negative feelings (Pérez-Edgar and Fox 2005). Behaviorally inhibited children show more negative cognitions and make lower estimates of their competency to cope with dangerous or stressful events (Pérez-Edgar and Fox 2005). This negative temperament is associated with enhanced amygdala activation in response to faces (Schwartz et al. 2003), which suggests that a neural “fear circuit” plays a role in this phenotype.

Individual differences in behavioral inhibition are apparent in early development, as are the asymmetries in mPFC activity discussed above (Davidson and Fox 1989). Thus, 10-month-old babies who cry in response to maternal separation are more likely to show greater right-sided prefrontal activation during a preceding resting baseline compared with those infants who did not cry. Rothbart and colleagues (Rothbart 2004) showed that infants prone to distress, suggesting increased behavioral inhibition, are less adept at shifting attention away from a distressing stimulus and have difficulty engaging in self-soothing activity. Such findings suggest an early developmental appearance of the problems with emotional regulation and patterns of neural activity that define an increased vulnerability for anxiety disorders. Dawson and colleagues (e.g., Dawson et al. 2003) showed that the offspring of depressed mothers show increased behavioral inhibition and greater baseline EEG activity in the right prefrontal cortex.

Familial Transmission of Risk: Effects of Genes, Environment, and Their Interaction

These findings raise the obvious issue of the familial transmission of the neural substrates for behavioral inhibition. Indeed, children of parents with anxiety disorders are more likely to show extreme behavioral inhibition (Rosenbaum et al. 1991). Moreover, unaffected siblings of anxious adolescents also show significant levels of emotionality and shyness. Behavioral inhibition appears heritable, with estimates ranging from 0.40–0.70 in twin studies (Pérez-Edgar and Fox 2005). For example, one study (Smoller et al. 2003) links behavioral inhibition and an allelic variation in gene for CRF. Auerbach et al. (2001) showed that variants of the 5-HT transporter gene are associated with negative temperament in infancy. The same allelic variation is associated with increased expression of the harm avoidance personality trait that includes increased fearfulness, shyness and timidity (Arbelle et al. 2003) as well as increased amygdala responses to emotional facial stimuli. These findings suggest that genomic variations might function in early development to regulate the development of neural systems that mediate emotional states. This idea is consistent with animal studies that reveal increased fearfulness in animals bearing a targeted disruption of the 5-HT1A receptor (Gross et al. 2000). Hen and colleagues (Gross et al. 2002) subsequently found that the critical period for the effect of the 5-HT1A knockout on anxiety-like behavior in adult animals was that of early development, when 5-HT actively regulates the growth and development of synaptic connections in regions such as the amygdala, hippocampus and mPFC. These regions are all major 5-HT targets.

These studies suggest that genomic inheritance describes, in part at least, the variance in behavioral inhibition across children. It is important to note, however, that estimates of heritability include the variation in traits associated with gene x environment interactions that might serve to modify the expression of behavioral inhibition over development. Thus, a critical issue concerns the stability of the traits that define behavioral inhibition (Fox et al. 2001). As young adults, children identified as behaviorally inhibited at two-years of age show greater activation of the amygdala in response to novel faces than do those that were characterized as behaviorally uninhibited as toddlers (Schwartz et al. 2003). Longitudinal studies report moderate stability (i.e., correlations of approximately $r = 0.25–0.60$) of behavioral inhibition from early to middle and late childhood through to early adulthood (Pérez-Edgar and Fox 2005). Stability is greater among extremely inhibited children. However, while the majority of adults with behavior problems initially developed signs of such problems as children, most behaviorally inhibited children do not develop anxiety disorders in later life. Such findings appear to reflect the importance of gene x environment interactions acting through development that determine cognitive-emotional outcomes. Fox and colleagues (Pérez-Edgar and Fox 2005) found that emotionally negative infants at 4 months of age are more likely to become less inhibited as toddlers when placed in nonparental care environments, such as daycare settings, for at least 10 hours per week. Family function, particularly parent-offspring interactions, also seems to be defined the developmental outcomes in behaviorally inhibited children. Rubin et al. (2002) found that behavioral inhibition at two predicted reluctance to interact with unfamiliar peers at four years of age only in mothers that were intrusive and critical. Hence parental style determines the developmental trajectory of behaviorally inhibited children. Bowlby (1960) associated anxiety with the quality of the mother-infant bond to the security of attachment and the fear of separation. Fleming (1988) found that the anxiety level of the mother was
the single best predictor of her level of responsivity to the infant. More anxious mothers were less responsive. These findings underscore the potential for intervention studies that target parental responses to more anxious or temperamentally infants. Indeed, the clinical literature supports the idea that such interventions yield significant results in offsetting the long-term risk for affective disorders (Belsky 1997).

These findings suggest that the developmental outcomes associated with behavioral inhibition in early life are modulated by environmental influences. This idea is consistent with findings from studies with nonhuman subjects that reveal direct effects of maternal care on neural systems that regulate fear. In humans, behavioral inhibition is associated with gene–environment interactions occurring in childhood (Fox et al. 2005), presumably through environmental regulation of the genes of which later regulate activity in neural circuits associated with fear and anxiety.

Levine and colleagues showed that a behavioral manipulation in infancy, handling, which consists of daily brief separation from the mother over the first two postnatal weeks, leads to resistance to the behavioral and endocrine responses to stress in adulthood. For example, handled infant rats had reduced glucocorticoid responses to active avoidance learning (Weinberg and Levine 1977), and the altered HPA response bias was lifelong (Meaney et al. 1988) due to permanently increased hippocampal type II glucocorticoid receptor binding (Meaney et al. 1991). Interestingly, postnatal handling of infant rat pups alters the behavior of the mothers. These effects appear to mediate, in part, the influence of the handling on stress reactivity. Subsequent studies on the effects of maternal care have provided direct evidence for parental influences on the development of neural circuits that regulate fear and anxiety (Meaney 2001, Zhang et al. 2006).

In the rat, naturally occurring variations in maternal care stably alter the expression of genes in brain regions, such as the hippocampus, amygdala and prefrontal cortex, that regulate behavioral, autonomic and endocrine responses to stress (Cameron et al. 2005, Meaney 2001, Zhang et al. 2006). These studies focus on individual differences in maternal behavior in the absence of any experimental manipulation of the mother or her pups, particularly one specific maternal behavior in the rat, pup licking. By licking her pups the mother regulates the activity of their endocrine systems that strongly influence somatic growth. Thus, licking enhances the circulating levels of growth hormone (Schanberg et al. 1984) and suppresses the release of the catabolic glucocorticoids (Levine 1994). Considering the effects on somatic development, we might think of pup licking as a rudimentary form of “nurturance.” And there are very stable, individual differences in the frequency with which rat mothers lick their offspring in early development. Importantly, these variations can directly “program” gene expression. For example, the adult offspring of high mothers that show high levels of licking over the first week of postnatal life have increased expression of GABA<sub>A</sub> receptor subunits in the amygdala, which confers greater sensitivity to GABA as well as to BZs and their anxiolytic effects (Fries et al. 2004). Predictably these adult offspring show decreased fearfulness, reduced fear conditioning and more moderate noradrenaline responses to stress (Caldji et al. 1998, 2003). Such effects target the α1 and γ2 subunits of the GABA<sub>A</sub> receptor, and selective knockdown of these subunits in mice results in increased fearfulness in response to novelty and enhanced conditioned emotional responses (e.g., Crestani et al. 1999). Recall that among human subjects, there is reduced sensitivity to BZs (which act at the α1 and γ2 subunits of the GABA<sub>A</sub> receptor) among those with an increased vulnerability for anxiety disorders (see above).

The effects of maternal care in the rat on the GABA<sub>A</sub> receptor system and fear behavior are reversed with cross fostering, revealing a direct maternal effect on the development of the GABA<sub>A</sub> receptor system (Caldji et al. 2003). Moreover, these same variations in maternal care also directly alter the expression of genes that promote synaptic development of the hippocampus (Liu et al. 2000), and individual differences in hippocampal morphology are associated with vulnerability for anxiety disorders (Gilbertson et al. 2002). Finally, maternal care over the first week of life in the rat also regulates the expression CRF and CRF1 receptors in the amygdala and the locus coeruleus (Caldji et al. 1998). The offspring of low licking mothers show increased CRF activity and, predictably, enhanced noradrenaline release in response to threat.

The results of Gilbertson et al. (2002) suggest that the reduced hippocampal volume commonly reported among PTSD patients is developmental in origin. Rodent studies suggest parental effects. Thus, the neonatal rats exposed to prolonged periods of maternal separation show reduced expression of brain-derived neurotrophic factor (BDNF) in the hippocampus (Roceri et al. 2002). BDNF stimulates synaptic development in the rat hippocampus, and elsewhere in the developing brain. Studies of naturally occurring variations in maternal care in this species show that maternal licking increases BDNF expression in the hippocampus (Liu et al. 2000). As adults, the offspring of high licking mothers show enhanced hippocampal synaptic density (Liu et al. 2000, Bredy et al. 2004). These findings suggest that maternal care can directly regulate hippocampal development, and there is at least correlational evidence for such an effect in humans (Buss et al. 2007). Interestingly, the antidepressant medications, often effective in the treatment of certain anxiety disorders, increase hippocampal BDNF expression (Tanis et al. 2007).

These findings suggest that parental care can directly regulate the development of neural and molecular substrates that are involved in emotion. One question concerns the mechanism by which parental care in early life might stably alter gene expression in the offspring. Recent studies in the rat suggest an epigenetic mechanism, that is, functional modifications to the DNA that do not involve a change in sequence. Such modifications commonly involve alterations in the methylation status of cytosines lying within the promoter regions of genes. DNA methylation is commonly associated with the silencing of gene expression. A recent set of studies (Weaver et al. 2004, 2005, 2007) found that pup licking by the mother alters the methylation state of a promoter for the glucocorticoid receptor in the hippocampus of the offspring. The offspring of high-licking mothers showed reduced methylation of the promoter and increased hippocampal glucocorticoid receptor expression. Such effects persist well into adulthood and are functionally relevant. The hippocampal glucocorticoid receptor inhibits CRF expression in the hypothalamus and thus regulates HPA responses...
to stress. The adult offspring of high-licking mothers show reduced hypothalamic CRF activity and more modest HPA responses to stressors than do animals reared by low-licking mothers. These effects, including those on promoter methylation, are reversed with cross-fostering, revealing direct maternal effects.

These findings suggest that, in the rat at least, maternal care can program defensive responses to threat. Interestingly, chronic stress during gestation reduces postpartum pup licking such that stressed mothers are low-licking mothers (Champagne and Meaney 2006). This pattern of maternal care results in more anxious offspring (Champagne and Meaney 2006). Under certain conditions, such effects might in fact be adaptive. Among humans, behavioral inhibition predicts greater success among young males living in poor, high-crime environments (Farrington 1988, Haapasap and Tremblay 1994). Such fearful boys are considered less likely to participate in criminal activity. Such potentially adaptive patterns of development come at a cost that is reflected in the increased risk for anxiety disorders. Indeed, low socioeconomic status is a risk factor for anxiety disorders.

The findings with nonhuman species suggest that variations in the quality of early parental care are relevant for individual differences in emotional reactivity, even for low-risk populations. This conclusion is supported by data in children from Hane and Fox (2006), who used standardized coding systems to score variations in child care (i.e., low quality versus high quality maternal care behavior). Infants receiving low-quality maternal care showed more fearfulness, less positive joint attention, and greater right frontal EEG asymmetry than infants receiving high-quality care. Group differences in stress reactivity were not related to infant temperament. The results suggest that variations in parental care in human infants may influence the development of neural systems involved in behavioral inhibition. In children, a disorganized infant–parent attachment relationship is associated with increased salivary cortisol, suggestive of greater stress reactivity (Nachmias et al. 1996). Among adult humans, Pruessner et al. (2004) found that individuals who report having had low-quality relations with their parents show significantly more release of dopamine in the ventral striatum, as evidenced by reduction in [11C]raclopride binding potential in PET scans, during a stressful event than individuals who report high-quality relations with their parents.

These findings suggest familial influences on the development of vulnerability for anxiety that are mediated by variations in parental care. More dramatic evidence for this effect emerges from studies of child maltreatment. Individuals abused in childhood are especially sensitive to facial expressions of anger, which is of course a very salient stimulus for children living in such harsh settings. Event-related potential (ERP) studies reveal that abused individuals, children or adults, show increased neural activity in response to angry faces; no such effect is apparent in response to happy or fearful faces. Interestingly, such individuals are likely to interpret anger in facial expressions that controls perceive as neutral. These findings reveal an increased sensitivity to social or interpersonal threat among abused individuals. Not surprisingly, abused individuals show an increased tendency for fear and social withdrawal (i.e., increased behavioral inhibition). Nevertheless, despite the very immediate and profound impact of parental abuse on the child, such experiences do not necessarily lead to psychopathology in adulthood. Studies of the risk for pathology among abused individuals reveal clear examples of the importance of gene–environment interactions. Thus, adult males who were abused as children are relatively protected from the development of antisocial personality by a functional polymorphism of the gene for monoamine oxidase that causes high expression of the enzyme.

As development progresses, environmental events more proximal to the onset of affective illness interact with other genes. Among individuals with the short allelic variant of the 5-HT transporter, which predicts an increased risk for anxiety (Lesch et al. 1996), major life stress in early adulthood results in a very substantial increase in depression (Caspi et al. 2003). Conversely among those carrying the long variant of the 5-HT transporter gene, adversity as a young adult had little effect on the probability of subsequent depression. In Rhesus monkeys (Suomi 1997), the peer rearing compared with the maternal rearing increases the stress reactivity. The Rhesus monkey shows a similar functional polymorphism in the 5-HT transporter gene promoter, and the effects of peer rearing on stress reactivity are substantially greater among animals with the short variant. Peer rearing has little effect among animals homozygous for the long allelic variant of the 5-HT transporter (Barr et al. 2004, Bennett et al. 2002).

The results presented above are often taken to reflect evidence for differences in vulnerability, and allelic variations at genomic sites such as the promoter region of the 5-HT transporter gene as “vulnerability genes.” This may not be the most fruitful interpretation. Individuals bearing the short allelic variant of the 5-HT transporter promoter are certainly more affected by parental care with respect to measures of stress reactivity (Rhesus monkey) or affective illness (human). Hence the allelic variant confers greater susceptibility to environmental influences (with respect to these specific outcomes). This reasoning is consistent with studies in child development demonstrating differential susceptibility to parental care as a function of infant temperament (frequent distress, crying and agitation; Belsky 1997). Interestingly, parental care may exert an even greater influence on developmental outcomes in more vulnerable populations (Belsky 1997) such as emotionally reactive children. For example, positive parenting (positive affection and sensitivity to the child) compared with negative parenting (irritable and intrusive control of the child) had a significantly greater effect on behavioral inhibition in childhood offspring of irritable and intrusive parents. This was a better predictor of measures of emotional development for more temperamentally difficult infants. Interestingly, there is also evidence that environmental conditions that influence the quality of parent–child relations have a larger effect on developmental outcomes in more temperamentally difficult infants. Thus, Crockenberg (1981) reports that the parental–social support was predictive, of infant attachment security but only in the case of highly irritable infants. Blair (2002) showed that an enriched rearing experience comprised of educational day care combined with home visiting and parent support over the child’s first three years of life
affected social and emotional development among children who were highly negatively emotional infants, with no such treatment effect with other infants. These findings reflect an increased response to enriched environmental conditions among infants with negative temperament suggesting an increase in susceptibility to environmental variation, rather than merely greater vulnerability to adversity.

These findings provide an understanding of the nature of the gene–environment interactions that might define individual differences in vulnerability for anxiety disorders. Heritable genomic variations as well as the quality of maternal–fetal interactions in prenatal life predict behavioral inhibition in the child, and such individual differences in temperament are apparent in early infancy (Thomas and Chess 1977). Individual differences in behavioral inhibition are associated with patterns of neural activity that they themselves are related to increased vulnerability for anxiety disorders. However, while behavioral inhibition in early life is a risk for anxiety in later life, the majority of behaviorally inhibited children do not develop anxiety disorders. Variations in child care are likely a critical factor in determining the developmental outcomes associated with states of increased vulnerability. Thus, Rubin et al. (2002) showed that increased behavioral inhibition in infancy predicted fear of interacting with peers only if parents were highly intrusive and controlling. Such forms of parenting are, of course, a function of the parents’ anxiety. It is precisely this level of complexity that reflects the consistent gene–environment interactions inherent in the familial origins of anxiety disorders.

**Conclusions**

Recent clinical research has clarified the criteria for the diagnoses of the anxiety disorders, clearing the way for major advances in the understanding of the pathophysiology of specific anxiety disorders such as PTSD and social phobia. Important findings have come from human neuroimaging and genomic studies. Current neuroimaging research highlights the reciprocal roles of the prefrontal cortex and the amygdala in the pathogenesis of anxiety disorders. Underactivity of the PFC and overactivity of the amygdala biases adults and children to perceive stimuli as threats and to react to them fearfully, thus predisposing them to anxiety disorders. Linkage and association studies of candidate genes have suggested a significant association between PD and a functional COMT polymorphism, while large cohort studies have implicated the interactions of specific alleles for serotonin and catecholamine signaling, the serotonin transporter and monoamine oxidase genes respectively, with specific environmental stressors particularly childhood abuse and major life adversity as risk factors for affective dysregulation. Animal models using transgenic, molecular biological, and pharmacological methods have demonstrated that normal anxiety responses depend on the presence of the CRF1 receptor, while anxiety modulation requires the integrity of the serotonin 1A and GABA_A receptors. Extinction and safety conditioning are separate forms of learning that depend on specific projections to the amygdala from the mPFC and striatum, respectively, which have implications for the treatment of PTSD.

Variations in early development, both genetically based and due to environmental factors, predispose to anxiety disorders. Behavioral inhibition, a moderately heritable trait, is a marker in infants of risk for anxiety disorders in adolescence, but the quality of parenting these infants receive is a mediating variable. Animal models of maternal care have made strides in our understanding of how early environment can produce lifelong biases towards anxiety responses to stress versus adaptive coping. The first two postnatal weeks are a critical period during which serotonin 1A receptors establish normal anxiety-like behavior in the adult. High levels of maternal care in the form of pup licking delivered in the first postnatal week results in adult resistance to behavioral and endocrine manifestations of stress-induced anxiety. Pup licking increases the expression of hippocampal glucocorticoid receptors which places the HPA axis under tighter negative feedback control. The mechanism of this increased expression may be via epigenetic reduction of gene silencing of a promoter region of the glucocorticoid receptor in the hippocampus. These findings may inform future approaches to early intervention of prevention of anxiety disorders.

Chapter 20 • Neurobiology of Anxiety Disorders

Further Reading

In his classic paper, Mourning and Melancholia, Freud provided a vivid clinical description of what we now call major depression, as well as a psychodynamic formulation. Freud acknowledged that some forms of depression were biological in origin. The past 40 years have witnessed a major effort to understand the biology of depression and the major affective disorder, manic depression. This chapter highlights the history of biological approaches to mood disorders and then reviews recent advances in understanding the neurobiology of these complex disorders.

Perhaps the major development in the past decade has been a shift from a view of depression as a relatively straightforward disorder of monoaminergic function to a more nuanced view of multiple causal steps ranging from alterations in neuronal second messenger systems to dysregulation of growth factor, peptide, and transmitter systems. These approaches have led to the investigation of decreased activity of neurotrophins and neurogenesis in specific brain regions and to altered activity in novel circuits. In each of these areas, available technology has generated new findings, which have spurred new theories of etiology.

Nomenclature

The modern era of biological research on affective disorders depended on the development of a reliable classification. Investigators in the United Kingdom and Germany took the lead in classifying depressions. Three major distinctions were made. The first distinguished endogenous from nonendogenous depression. Endogenous depression referred either to a depression that was not precipitated by external events or to depression with prominent biological symptoms akin to melancholia. Over time it was recognized that some patients developed severe melancholic depressions that were clearly precipitated, so that the diagnostic significance of external precipitation for major depression was dropped in the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, Third Edition (DSM-III). The second distinction was the qualifier psychotic versus nonpsychotic. Originally connoting severe or nonreversible, a psychotic affective disorder came to mean “characterized by delusions or hallucinations”.

The last distinction separated unipolar depression from bipolar, or manic-depressive disorder. Emil Kraepelin, whose nosology of major psychiatric disorders anticipated DSM-III, saw severe recurrent unipolar depression as a form of manic-depressive illness. Over time, family history data and risk for mania in probands led to a distinction between the two disorders, which is reflected in the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR). More recent interpretations of evidence from family studies, adoption studies, and susceptibility gene studies have blurred this distinction, suggesting that unipolar depression and bipolar disorder are on a continuum of major affective disorders. Some of this evidence for this view is discussed below.

Major depression today is characterized in DSM-IV-TR by the presence of five of nine possible symptoms that last for at least 2 weeks. These symptoms include low mood, decreased energy or agitation, impaired concentration, anhedonia, sleep disturbance, appetite disturbance, suicidal ideation, guilt, and diurnal variation. These were derived empirically and while reliable, their validity has not been demonstrated definitively. The syndrome of major depression can be further specified as melancholic, atypical, or severe and as with or without psychotic features. There
are some data to support these differentiations; however, debate continues on the optimal subclassification of depressive disorders.

Two symptom clusters that are common in depression but that are not included as specific criteria for a major depressive episode are anxiety and chronic pain. Both are seen in some 45–75% of depressed patients but neither are core criteria. Anxiety was not included in part because there was an inherent bias in DSM-III and DSM-IV-TR to distinguish between anxiety and depressive disorders. However, these symptoms frequently co-occur. Pain was not included because at the time DSM-III and DSM-IV-TR were written there was little epidemiologic data to indicate how commonly it accompanied depression or whether the comorbidity that was seen in medical settings generalized to broader populations. Recent data indicate that chronic pain is common in depressive subjects in the community.

Bipolar disorder includes manic or hypomanic episodes alternating with depressive episodes, with periods of normal mood between episodes. The diagnostic criteria for a manic episode include a cluster of symptoms lasting at least one week: euphoric or irritable mood accompanied by psychomotor acceleration or agitation, impulsivity, hypersexuality, inflated self-esteem or grandiosity, pressured speech, which is rapid and difficult to interrupt, and flight of ideas, a stream of thoughts that are only loosely connected. The distinction between full-blown mania and so-called hypomania, which is rapid and difficult to interrupt, and flight of ideas, a stream of thoughts that are only loosely connected. The distinction between full-blown mania and so-called hypomania is one of degree. The depressive episodes of bipolar disorder are phenomenologically indistinguishable from unipolar depressions.

**Genetics**

**Behavioral Genetics**

**Family, Twin, and Adoption Studies**

Family, twin, and adoption studies provide inferential statistical evidence for genetic and/or environmental contributions to the etiologies of mood disorders. Family studies provided the initial evidence of the possibility of a genetic basis for mood disorders. Family studies demonstrated familial clustering among first-degree relatives for both unipolar and bipolar disorders. A review of family studies by McGuffin and Katz (1986) covered the findings for both. Bipolar disorder was found to have an average lifetime morbidity risk among first-degree relatives of 8% compared to a base rate of 1% in the general population. For unipolar major depression the rates were nine and 3%, respectively. Family studies also revealed that first-degree relatives of bipolar depressed probands are more likely than persons in the general population to experience unipolar depression, whereas patients with unipolar depression are not at increased risk for bipolar depression. One interpretation of this asymmetry is that unipolar and bipolar depression may not be fully distinct diagnostic categories, but rather comprise a dimension on which unipolar depression is less severe than bipolar disorder.

Family studies have also served as initial tests of the validity of some of the subtypes of affective diagnoses discussed above. For example, family studies have not supported the reactive versus endogenous distinction. On the other hand early onset depression appears to be a more severe form of unipolar depression, if not a separate category, because when offspring of patients with early onset major depression (i.e., before age 20) are compared to offspring of parents with later onset major depression, the former are twice as likely as the latter to themselves suffer at some point from depression (Weissman et al. 1988). Some family studies of therapeutic response to medications have observed familial trends (Tsuang and Faraone 1990).

Family studies showing a correlation between genetic relatedness and disease risk cannot separate the contributions of genetic relatedness from that of shared environment. However, twin and adoption studies do address that distinction. Twin studies can be thought of as human experiments of nature in which the independent variable is the degree of genetic relatedness (mono- versus dizygous twins), while the environment is constant (under the so-called equal environments assumption, that the amount of shared environment within monozygous and dizygous twin pairs is the same). By contrast in adoption studies the environment varies. Twin studies estimate heritability of a disease by comparing the rate of concordance for a disease in monozygous versus same-sex dizygous twin pairs. The degree of shared environment is assumed to be unaffected by whether the twins are mono- or dizygous. An approximation of the degree of shared environment is obtained by doubling the difference in concordance rates between the monozygous and dizygous samples.

Twin studies have provided strong evidence for a genetic contribution to the causation of both unipolar depression and bipolar disorder, with bipolar disorder tending to show higher heritability than unipolar depression. Such studies also indicate that genetic predispositions to mood disorders are generally higher when measured in samples of probands that have more severe cases, as indicated by hospitalization. Various studies have suggested heritabilities for bipolar disorder ranging from 64% (Allen 1976) to effectively 100% (Bertelsen et al. 1977), and in aggregate suggesting a heritability of about 80%. These same studies and two others of unipolar depressed hospitalized patients (McGuffin et al. 1996, Torgersen 1986) found monozygous twin concordances of about 40% and dizygous concordance rates ranging from 11–20%, suggesting a heritability up to 50%. Studies among population-based samples of twins, which include a majority of less severe cases of depression, generally reveal less heritability. Importantly, if concordance among monozygous twins for a disorder is less than 100%, there must be nongenetic components of the risk for that disorder. Thus, the twin studies of the major affective disorders suggest that there are important, though unspecified, environmental components to the pathogenesis of these disorders, especially unipolar depression.

Adoption studies have confirmed the twin-study evidence of a substantial genetic contribution to bipolar disorder. The so-called adoptees’ study method separates genetic from environmental influences by comparing disease rates of adopted offspring of affected biological mothers and unaffected biological mothers. Another common design, the adoptees’ family method, compares rates of the disease in the first-degree relatives of affected and unaffected adoptees. The rate of disease concordance of adoptive offspring with their biological relatives is used as an index of heritability, while the concordance of the adoptive offspring with their
adoptive relatives provides an estimate of the influence of shared environment. Mendlewicz and Rainer (1977) found that among adoptees with bipolar disorder versus control adoptees, 7% of biological parents of bipolar adoptees had bipolar disorder as opposed to none of the biological parents of the control adoptees. The rates of bipolar disorder in the adoptive parents of both groups did not differ substantially. Taken together, the data of this study are consistent with a predominant genetic contribution to bipolar disorder. The evidence for genetic contributions to unipolar depression from adoption studies is less clear-cut. However, the study by Mendlewicz and Rainer (1977) strengthens the impression from family studies for a genetic overlap between bipolar disorder and unipolar depression. Specifically, biological parents of bipolar adoptees had a rate of unipolar depression of 21% compared with 2% among the biological parents of control adoptees.

**Susceptibility Gene Discovery for Affective Disorders**

Evidence from twin or adoption studies that a disorder is heritable implies the existence of genes that confer risk for that disorder. No common psychiatric disorder has been found by study of family pedigrees to follow simple single gene Mendelian inheritance patterns. Most psychiatric disorders are polygenic, that is, they result from the combined effects of variants of multiple genes each of which is responsible for a relatively small proportion of risk for the disorder. The identification of specific genes opens up the ability to directly investigate molecular mechanisms of psychiatric diseases leading from genotype through cell biology and neural circuitry to behavioral phenotype, paving the way for more effective and more specific treatments and perhaps prevention.

The techniques that are used to identify specific candidate susceptibility genes include cytogenetics, linkage analysis, positional cloning, and association studies. Studies testing the association of candidate genes with a disease of interest must have appropriate control samples. Generally the unaffected comparison group and the affected subjects should be drawn from the same ethnically homogeneous population to control for genetic background. If an association is found, the gene’s role as a susceptibility gene for the disorder must be validated by replication in other populations.

Among the first susceptibility genes to be identified was that for the serotonin transporter, the protein responsible for the reuptake of the neurotransmitter serotonin at synapses. This protein is the target of the most commonly used antidepressant medications, the serotonin selective reuptake inhibitors. Studies have implicated polymorphisms in the promoter region and in an intron of this gene. A Croatian study compared patients with major depression with healthy controls on two polymorphic regions of the serotonin transporter gene, a 44-base pair insertion/deletion in the promoter region and a variable number of tandem repeats in the second intron (Rozina et al. 2006). In this study, the short allele of the polymorphism in intron 2 was associated with major depression.

The human genome project has facilitated the task of identifying susceptibility genes. Many studies exploit the mapping on the genome of thousands of single nucleotide polymorphisms (SNPs), which can be detected in the DNA of subjects and are used to pinpoint the location and identity of the allele associated with the disease of interest. Thus, the number of genes implicated in the causation, severity, or treatment responsiveness of mood disorders has proliferated. Some of these have been identified by just one study, often in relatively homogeneous samples from one ethnic group or one country, and require replication for validation.

Using SNP technology, the gamma amino butyric acid (GABA) transmitter system has been studied for a possible role in the genetics of depression. From a population based twin sample, cases and controls were selected for having extreme high or low scores on a genetic factor representing major depression and several anxiety-disorder diagnoses (Hettema et al. 2006). This genetic risk factor was tested for its association with SNPs in the genes of two enzymes that synthesize GABA from glutamate, glutamic acid decarboxylase (GAD) 1 and 2. Several of the 6 SNPs tested in GAD1 were associated with the pathologies of interest and formed a common high-risk haplotype that was more frequent in cases than controls.

Another recent study investigated 21 SNPs in a family of genes for cyclic phosphodiesterase nucleotides, which hydrolyze the intracellular second messengers cAMP and cGMP (Wong et al. 2006). Because this degradation of these second messengers has the effect of downregulating the cell’s response to extracellular signals such as neurotransmitters, hormones and growth factors, PDE genes were considered as depression susceptibility candidates. Polymorphisms in the gene for PDE11A in Mexican Americans were found to be associated with either the diagnosis of major depression or with antidepressant-induced remission from it. In addition a specific haplotype, GAACC, was found to be significantly associated with depression. Further SNPs in PDE9A and PDE1A were associated either with the diagnosis or with therapeutic response, respectively.

The angiotensin converting enzyme (ACE) gene has also been considered a potential candidate gene for depression for two reasons. First because of ACE’s putative influence on the hypothalamic-pituitary-adrenal axis, which is hyperactive in a large proportion of patients with major depression, and second because this gene is known to be associated with cardiovascular disorders, which themselves are correlated with risk for major depression. Thirty-five SNPs in this gene were tested among patients with unipolar depression and controls (Baghai et al. 2006). Using an internal replication strategy, one SNP, rs4291, located in the gene’s promoter region was found to be significantly associated with a diagnosis of depression. Furthermore, the T-allele of this SNP was associated with depression and the depressed T-allele carriers had both high ACE serum levels and hypothalamic-pituitary-adrenal (HPA) axis activity, suggesting that this allele could represent a common risk for both depression and cardiovascular disease.

In light of this finding, it may not be surprising that evidence for another susceptibility gene involved directly in the regulation of the HPA axis, the glucocorticoid receptor, has been found. HPA axis dysfunction found in major depression may be due to impaired glucocorticoid signaling, perhaps mediated by the glucocorticoid receptor. The N363S and BCII polymorphisms are associated with glucocorticoid hypersensitivity whereas the ER22/23EK polymorphism is...
correlated with resistance to glucocorticoids. Four hundred and ninety depressed inpatients and 496 healthy controls were genotyped and investigated for HPA axis function and response to antidepressant treatment (van Rossum et al. 2006). Significantly, more depressed patients than controls were homoygous for BCI or carried the ER22/23EK polymorphism. In addition, the ER22/23EK polymorphism was associated with faster response to treatment.

The P2RX7 gene is a purinergic adenosine triphosphate (ATP)-binding calcium channel expressed in certain brain neurons and microglial cells. This gene was considered to be a candidate risk gene for depression because of its location in a in a chromosomal region, chromosome 12q24.31, that had previously been found by linkage and association studies to be a susceptibility locus for mood disorders. German patients with major depression were compared with controls from the same population for the presence of 29 SNPs in or near the P2RX7 gene (Lucae et al. 2006). One nonsynonymous SNP within the coding region of the P2RX7 gene, rs2230912, was found to be significantly associated with major depression. This SNP alters the amino acid in the C-terminal cytosolic domain of the P2RX7 channel protein. Importantly, this same SNP had previously been found to be associated with the diagnosis of bipolar disorder, providing molecular evidence of the suggestions from family studies that unipolar major depression and bipolar disorder lie on a severity dimension of mood disorders.

Some studies have focused on the genetic predisposition for the comorbidity of depression and another illness. For example, the short variant of the functional polymorphism in the serotonin transporter linked promoter region (5-HTTLPR) was associated with post-stroke depression (Ramasubbu et al. 2006). Other studies have focused on genetic predispositions for specific clinical features of depression such as suicide and self-injurious behavior. One study, using DNA extracted from blood or frozen brain tissue, compared depressed patients who had completed suicide with depressed controls on the frequencies of two polymorphisms in the serotonin transporter gene. These polymorphisms are the same ones that were studied for an association with the diagnosis of depression in the Croatian sample discussed above (Bozina et al. 2006). Namely, a 44-base pair insertion/deletion in the promoter region, and a variable number of tandem repeats in intron 2, containing either 9, 10, or 12 copies of a 17-base pair element. Both of these polymorphisms affect the expression level of the gene. There was a significant association between completed suicide and the intron 2 variant containing 10 copies of the repeated element, which has lower expression than the 12 repeat allele (Lopez de Lara et al. 2006). Another study found that patients with depression who carry the T allele of G protein beta3 (GNbeta3) were more likely to engage in self-mutilating behaviors (Joyce et al. 2006), especially younger depressed patients.

Candidate genes chosen for investigation because of their plausibility for a functional role in bipolar disorder include some involved in neurotransmitter systems that regulate of mood states. Meta-analyses of studies of relatively small samples have yielded significant evidence for three such genes each with small effects: monoamine oxidase A (MAO-A) (Preisig et al. 2000), an enzyme associated with the outer mitochondrial membrane and distributed widely in the brain, which metabolizes the neurotransmitters, norepinephrine (NE) and serotonin; catechol-O-methyl transferase (COMT) (Jones and Craddock 2001), the enzyme most responsible for the metabolic inactivation of the neurotransmitter dopamine in the prefrontal cortex; and the serotonin transporter (5-HTT) (Anguelova et al. 2003), which inactivates serotonin released into synapses by returning it to the presynaptic cell ending. The locus for the d-amino acid oxidase activator (DAOA) gene, originally reported to be in linkage disequilibrium for schizophrenia, has recently been found in U.S., German, and British samples to be in linkage disequilibrium with bipolar disorder (Chen et al. 2004, Schumacher et al. 2004, Williams et al. 2006). There is as yet no evidence for a functional or pathological mechanism; however, the gene for d-amino acid oxidase (DAO), which is activated by DAOA, lies in a region that has been implicated in recent genome scans, the 12q23 region (Ewald et al. 2002, Shink et al. 2005).

Finally, there is evidence for brain derived neurotrophic factor (BDNF) as a susceptibility gene. It affects multiple neural processes central to current hypotheses of mood disorders, that is, those involving loss of synaptic plasticity due to chronic stress and affects the actions of antidepressants (see below). In the developing brain BDNF is important in the growth and survival of certain types of neurons; it is involved in activity-dependent plasticity in the mature brain (Duman 1999). The gene for BDNF is located in the chromosomal region 11p13, which has been implicated in some linkage studies of bipolar disorder. A single SNP, which codes for an amino acid substitution of the amino acid valine to methionine in the pro-BDNF precursor molecule, could potentially be responsible for functionally important differences in the processing of BDNF itself. Three family association studies of Caucasian samples revealed a higher proportion of the valine (Val) allele in bipolar individuals (Sklar et al. 2002, Neves-Pereira et al. 2002, Geller et al. 2004). This association has not been found in other populations (Skibinska et al. 2004, Hong et al. 2003). One study found an association between the Val allele and rapid cycling within the bipolar group (Green et al. 2006).

Gene Environment Interactions
As suggested above, the major affective disorders cannot be explained either by genetic susceptibility or environmental factors alone. Twin and adoption studies of mood disorders generally indicate higher heritabilities for bipolar disorder than for unipolar depression. The corollary of these findings is that environment may play a larger role in the causation of unipolar depression than bipolar disorder (Paykel 1994, Paykel 2003). Pending the conclusive demonstration of specific environmental risks in human depressive disorders, some animal models, discussed below, have begun investigating the possible mechanisms of candidate environmental insults that are suggested by human population and clinical studies. However, such studies cannot address a larger question, namely by what mechanisms do environmental insults precipitate depression in some people but not others. This question is addressed by interesting recent studies designed to detect interactions between specific candidate risk genes and specific candidate environmental insults in
mood disorders. This design has the potential to not only discover these kinds of interactions, but also to potentially reveal novel susceptibility genes that may act only under certain adverse environmental conditions and would otherwise remain unknown.

A functional variable number tandem repeats (VNTR) polymorphism in the promoter region of the serotonin transporter gene (5-HTTLPR) produces short (s) and a long (l) sequence variants. The s variant is associated with lower transcription efficiency of the promoter than the l variant, resulting in less mRNA and protein (Lesch et al. 1996). Eight hundred forty-seven 26-year-olds in a New Zealand birth cohort were genotyped for the 5-HTTLPR s and l variants (Caspi et al. 2003). Fourteen kinds of serious stressful life events that occurred in the prior 5-year interval were determined by self-report. There were no differences across the genotypes in the number of stress events experienced. A standardized questionnaire based on DSM-IV-TR, and informant reports, were used to quantify depressive symptoms and detect the diagnosis of an episode of major depression in the year prior to the study. Statistical analyses revealed that the impact of life events on depressive symptoms and on the categorical diagnosis of major depression was significantly stronger in individuals carrying one or two copies of the s allele versus individuals who are homozygous for the allele. A parallel finding applied to suicidal ideation or suicide attempts: that is, stressful life events predicted these symptoms in carriers of the s allele but not in l homozygotes.

One study extended this result to depression during adolescence: an interaction between the 5-HTTLPR polymorphism and environmental risk in was found for females (Eley et al. 2004). Studies with similar designs in samples of older individuals have not consistently replicated the effect (Wilhelm et al. 2006, Gillespie et al. 2005, Surtees et al. 2006). Thus the interaction may occur primarily in younger persons.

Each susceptibility gene discovered to date accounts for only a small proportion of the variance in the population for the occurrence of a mood disorder. Thus mood disorders may require the additive or interactive effects of multiple genes as well as the interactions of genes and environmental conditions. The gene by environment interaction design has been elaborated in more complex designs that can detect gene by gene as well as gene by environment interactions. For example, early maltreatment places children at risk for depression, yet some succumb to the disorder while others are resilient. A study tested whether gene by gene or gene by environment interactions may explain the differences and whether social support moderates the risk. One hundred nine abused children and 87 nonabused controls were genotyped for alleles in two genes implicated as susceptibility genes for depression: (1) the VNTR short variant of the 5-HTTLPR and (2) the BDNF Val66Met substitution, both discussed above. There was a significant three-way interaction between the 5-HTTLPR and BDNF genotypes and maltreatment. Children with both copies of the 5-HTTLPR s allele and the Met substitution for BDNF were most vulnerable to depression, but only if they were maltreated. There was also a significant four-way interaction in which social supports moderated the risk for depression.

Gene Expression in Mood Disorders
The use of microarrays provides an approach for high throughput expression profiling of the entire human genome, offering the potential to identify genes whose altered expression could contribute to neuropsychiatric illnesses. However, the application of this approach to complex, heterogeneous tissue such as brain poses novel challenges for optimizing signal strength and achieving sufficient sensitivity to observe small changes. In addition, validating identified gene expression changes and elucidating the role of these genes in behavioral abnormalities poses further challenges. In spite of these problems, recent studies have begun to make progress in profiling gene expression changes in mood disorders.

Two studies have focused on subfamilies of genes that have been implicated in mood disorders based on preclinical and clinical work. The first of these demonstrates altered expression of genes in the fibroblast growth factor (FGF) family in postmortem tissue of depressed subjects relative to matched controls (Evans et al. 2004). This includes decreased expression of FGF-2 and FGF receptors 2 and 3 in regions of the prefrontal and cingulate cortices implicated in depression. These effects were observed in two separate cohorts of depressed subjects, providing evidence of the replicability of these effects. A role for FGF-2 in depression is also supported by preclinical studies demonstrating that the expression of this factor is increased by antidepressant treatment (Mallei et al. 2002) and more generally by evidence for a neurotrophic hypothesis of depression (see below).

A second paper from this group highlights altered expression of molecular components of the glutamate and GABA neurotransmitter systems (Choudary et al. 2005) in major depressive disorder and bipolar disorder. This study reports that the patients with major depression had decreased expression of genes in the prefrontal cortex that control synaptic and extrasynaptic levels of glutamate. Reduced expression of these genes, two types of glutamate transporters and an enzyme that converts glutamate to non-toxic glutamine could result in excessive levels of glutamate and, as a consequence, neurotoxic damage. The astroglial localization of these glutamate signaling regulators is evidence of glial cell involvement in depression and is consistent with reports of decreased neuroglia in depressed subjects (Ongur et al. 1998, Rajkowska et al. 1999, Cotter et al. 2001). This study also reports altered expression of several glutamate and GABA receptor subunits in major depression and bipolar disorder, and two GABA receptor subunits in patients with either diagnosis who had suicided. Additional studies will be needed to confirm these findings and further characterize the gene expression changes in depressed subjects, as well as studies to determine the functional significance of these changes.

Pathogenic Mechanisms
Transmitter Systems
The earliest approaches to the biology of depression revolved around (1) the function of neural monoamines, particularly the catecholamine; NE, or noradrenaline, and the indoleamine; serotonin and (2) neuroendocrine function, particularly the HPA axis, which is responsible for the synthesis and release of the stress hormone, cortisol. The
hypothesis that monoaminergic systems were dysfunctional in depression was first suggested by clinical pharmacologic observations, the so-called psychopharmacologic bridge, that: (1) the antihypertensive agent, reserpine, depleted monoaminergic stores and caused depression in some individuals, (2) monoamine oxidase inhibitors (MAOIs), which metabolize bioamines in neurons and were originally used to treat tuberculosis, were potent antidepressants, and (3) the tricyclic antidepressant (TCA), imipramine, blocked the reuptake of NE into presynaptic neurons and improved mood. Initially American researchers focused on the NE hypothesis (Bunney and Davis 1965, Schildkraut 1965, Schildkraut and Kety 1967) whereas British researchers favored an indoleamine hypothesis (Coppen 1968). Schildkraut 1965 and Schildkraut and Kety (1967) noted that a functional deficiency of NE appeared to be associated with depressive states and a functional excess of NE seemed to be associated with elation, implying a role for catecholamine transmission in the mechanisms of both depression and mania. Coppen’s (1968) paper suggested parallel actions of serotonin. Early animal models and additional observations from clinical psychopharmacology bolstered these hypotheses. For example, in rats, stress caused alterations in behavior and in NE turnover, some of which were reversed by antidepressants. The introduction of the tricyclic and selective serotonin reuptake inhibitor (SSRI) classes of antidepressants, which inhibit the actions of the NE and serotonin transporter molecules, strengthened the psychopharmacologic bridge.

The psychopharmacologic bridge hypothesis received support from studies of cerebrospinal fluid in which levels of the serotonin metabolite, 5-hydroxyindoleacetic acid (5-HIAA) were noted to be decreased in depressed patients who later suicided especially by violent means. Altered transport activity in blood components and decreased binding for serotonin reuptake in depressed patients, using displacement of the serotonin reuptake inhibitors imipramine, a TCA, and paroxetine, an MAOI, was demonstrated. Delgado and Charney developed an elegant tryptophan depletion strategy. Depressed patients who had responded to SSRI antidepressants demonstrated relatively rapid relapse of symptoms when placed on a diet that was low in tryptophan, the serotonin precursor (Delgado et al. 1999). They similarly demonstrated that chemically inhibiting the biosynthesis of NE would precipitate relapse in patients who had responded to noradrenergic agents (Hening et al. 1996).

However, the initial central amine hypothesis proved to be simplistic, as shown by a large body of research using indirect measures of NE and serotonin function beginning in the late 1970s. Because brain tissue levels of the central amines and their associated enzyme and transporter molecules could not be measured, biochemical indices of NE and serotonin function were measured in the periphery and were assumed to be proxies for brain central amine function. Such studies began to reveal the complexity of the role of central amines in major affective disorders. For example, urinary excretion of the NE metabolite 3-methoxy-4-hydroxyphenylglycol (MHPG), viewed as an index of norepinephrine turnover in the brain, was found to be lower in bipolar depression than in either unipolar depression or controls and was heterogeneous in unipolar depression (Schatzberg et al. 1982).

At the same time, abnormalities in the enzymes and transporter molecules that inactivate NE and serotonin in extracellular spaces and synaptic clefts were hypothesized to account for the altered function of these transmitters in mood disorders. Platelet MAO activity was used as a presumptive marker for the activity of brain MAO, which metabolizes both NE and serotonin. These studies showed intriguing but inconsistent differences between platelet MAO activity in unipolar depressives, bipolar depressives, and well controls (Edwards et al. 1978, Samson et al. 1985). A related hypothesis, based in part on animal lesion studies (McIntyre et al. 1984) and on correlations found in clinical samples, suggested that serotoninergic activity regulates the activity of the HPA axis. This was of interest because cortisol hypersecretion in some patients with endogenous depression (see below) was postulated as a pathogenic mechanism. Thus, the central amine hypofunction and HPA hyperfunction hypotheses were linked by the hypothesis that high MAO activity in depressed patients, which would suggest low serotonin activity, might be associated with hypersecretion of cortisol. Several studies found that platelet MAO activity had a positive correlation with nonsuppression of serum cortisol following administration of the synthetic glucocorticoid dexamethasone in major depression but not in bipolar depression (Schatzberg et al. 1983, Bagdy et al. 1986, Pandey et al. 1992).

Direct study of the aminergic neurotransmitter systems in postmortem brain tissue has been ongoing for several decades and since the 1990s has benefited from the use of modern, the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R), diagnoses established from premortem medical records or structured interviews of the next of kin. Reviewing postmortem studies of bipolar disorder, Vawter et al. (2000) concluded that NE turnover, as measured by the ratio of NE’s main metabolite, 3-methoxy-4-hydroxyphenylethlyleneglycol (MHPG), to NE, may be increased in areas of the cortex and thalamus, while 5-hydroxyindoleacetic acid (5-HIAA), the main metabolite of 5-HT, and the serotonin transporter (5-HTT) may be reduced in the cortex. Membrane suspensions from postmortem tissues are used to test the functional levels of the aminergic neurotransmitter receptors. These receptors are coupled to G-proteins located on the cytoplasmic side of the cell membrane, which transduce the extracellular neurotransmitter signal into second messenger intracellular signals. When a neurotransmitter molecule binds to its receptor, the activated G-protein exchanges a guanine diphosphate (GDP) molecule for a guanine triphosphate (GTP). This process can be quantified by measuring the binding of a radiolabeled GTP analog to the G-protein. This method has demonstrated that in the frontal cortex presynaptic 5HT2A autoreceptors, which decrease the release of NE, are four times more sensitive in suicide victims with mood disorders than those of controls (González-Maeso et al. 2002). Clearly investigating postmortem brain tissue provides the ability to study anatomic structures at very fine levels of resolution. Such studies must use age, gender, and postmortem interval-matched controls. However, important limitations include the availability of brains for sufficiently large sample sizes, the possible effects of various causes of death, including suicide, and whether an episode of the
Neuroendocrine Systems: Role of the Hypothalamic Pituitary Adrenal Axis

The observation of a strong positive correlation between urinary MHPG and cortisol (Rosenbaum et al. 1983) established a coupling between the catecholamine and HPA axis function. Dysregulation of circadian rhythms of neurohormone and neuroendocrine secretion has been proposed as a mechanism of depression. Koenigsberg et al. (2004) found evidence that the coupling of the circadian rhythms for the secretion of NE, cortisol, and other neurohormones such as growth hormone and prolactin measured in serum, are phase advanced and possibly out of synchrony. Neuroendocrine approaches to mood disorders begin with observations that stress in humans was associated with the release of cortisol from the adrenal cortex in parallel with the release of catecholamines from the adrenal medulla. In particular investigators began to describe abnormalities in the diurnal rhythm of the secretion of cortisol in major depression. Sachar’s group demonstrated elevated pulses of cortisol in severely depressed patients particularly at night (1973). Some depressed patients were also found to lack the normal suppression of cortisol release after the administration of a synthetic glucocorticoid, dexamethasone, which works via the hypothalamic-pituitary-adrenal axis feedback loop. Although nonsuppression of cortisol by dexamethasone is not a specific test for melancholia, at least two metanalyses have supported the observation that the test is highly abnormal in depressed patients with psychosis.

Cortisol release from the adrenal gland is stimulated by adrenocorticotropic hormone (ACTH) from the anterior pituitary, which in turn is controlled by corticotropin releasing hormone (CRH) produced in neurosecretory cells of the paraventricular nucleus of the hypothalamus and transported to the pituitary via a portal circulation. Investigators have demonstrated depressogenic effects of CRH in rats and monkeys. CRH levels have been reported to be elevated in depressed patients, while depressed patients have a blunted ACTH response to CRH in comparison to healthy controls.

The characterization of two brain receptors for cortisol was a further advance in understanding the role of the HPA axis in the pathogenesis of affective disorders. Mineralocorticoid receptors are high affinity receptors found largely in the hippocampus, whereas glucocorticoid receptors are low-affinity and distributed broadly throughout the brain. Mineralocorticoid receptor activity tends to maintain homeostasis by limiting the physiologic perturbation caused by a stressor, while glucocorticoid receptors contribute to recovery after the stress challenge (de Kloet and Derijk 2004). An imbalance of brain mineralocorticoid and glucocorticoid receptor activities is hypothesized to underlie HPA axis dysfunction and stress-related behaviors. Over activity of cortisol in the brain has been hypothesized to play a role in psychotic depression (Keller et al. 2006), with excess secretion of cortisol occurring during the evening nadir in psychotic depressed patients compared to nonpsychotic depressives and normal controls. Glucocorticoid synthesis inhibitors and antagonists of CRH and of glucocorticoid receptors are under active investigation as treatments for psychotic and nonpsychotic depression (Norman and Burrows 2007).

Genetics has opened up other new avenues to explore the HPA axis and its relationship to depression. Co-chaperone and chaperone proteins for the glucocorticoid receptor have been identified and SNPs for a co-chaperone have been reported to be associated with greater cortisol responses to dexamethasone-CRH challenge and to be associated with rapid antidepressant response as well as a greater prevalence of relapse. Similarly, genetic glucocorticoid receptor variations have also been identified and may have predictive value for medical illnesses as well as depression.
Section III • Neuroscientific Foundations

Intracellular Signal Transduction Pathways and Growth Factors

The actions of neurotransmitter and endocrine systems on neuronal function are mediated by regulation of complex intracellular signaling pathways. Elucidation of the alterations of these pathways in depression and the influence of antidepressant treatment on these pathways provides insights on the pathophysiology and treatment of mood disorders. This section highlights and discusses a few of the key signaling pathways, the cAMP response element binding (cAMP-CREB) and mitogen-activated protein (MAP) kinases pathways, that have been implicated in the mood disorders. These signaling cascades have also been implicated in learning and memory and are discussed in other chapters in this volume. Other pathways to consider include the phosphatidylinositol pathway and glycogen synthase kinase cascade, both of which have been implicated in the actions of mood stabilizing agents as well as antidepressants, (see Manji et al. 2001, Nestler et al. 2002, Coyle and Duman 2003, Einat and Manji 2006).

Cyclic AMP–CREB Cascade

Receptor Coupled cAMP Signaling System

The cAMP system is one of the earliest identified and characterized intracellular signaling pathways. This pathway is comprised of adenyl cyclase, the enzyme that catalyzes the formation of the second messenger cAMP, and stimulatory and inhibitory G proteins, Gs and Gi, that couple to neurotransmitter receptors that either activate or inhibit formation of cAMP (Nestler and Duman 2006). There are several NE and 5-HT receptors that couple to the cAMP cascade, including stimulatory (β2-adrenergic, 5-HT1B, 5-HT2c and 5-HT7) and inhibitory subtypes (α2-adrenergic, 5-HT1A, 5-HT1B, and 5-HT1D to name a few). There are also several isoforms of adenyl cyclase that differ in sensitivity to regulation by Ca2+/calmodulin as well as in their ability to free another G protein subunit, Gb. The actions of cAMP are mediated by activation of cAMP-dependent protein kinase (PKA), which regulates many cellular proteins via phosphorylation. One of the key factors that underlies the actions of receptor coupled cAMP signaling on gene expression is the phosphorylation and activation of the transcription factor, CREB protein. The receptor coupled cAMP system has been the focus of depression research for over 25 years and this work has contributed to our understanding of the actions of antidepressant treatments.

Regulation by of the cAMP-CREB Cascade by Antidepressant Treatment

Early studies reported that the ability of b-adrenergic receptors to stimulate cAMP formation is decreased by antidepressants, leading to the hypothesis that the actions of these treatments is mediated by desensitization of this receptor coupled second messenger system (Banerjee et al. 1977). However, subsequent studies of the intracellular components of this cascade demonstrate the opposite effect, that this pathway is up-regulated by antidepressants. This includes increased coupling of Gs-adenyl cyclase, increased levels of PKA (Nestler et al. 1989, Perez et al. 1989), and increased levels of CREB (Nibuya et al. 1996, Thome et al. 2000). In addition to PKA, CREB is also regulated by other signaling pathways, including Ca2+/calmodulin dependent PKAs and MAP-extracellular-signal-regulated kinase (MAP-ERK) signaling cascades, which also have been implicated in the actions of antidepressant treatment (see below, and review by Tardito et al. 2006).

These studies illustrate an important concept when interpreting neurotransmitter receptor data, particularly from in vitro studies but also in vivo receptor imaging studies. Although antidepressant treatments increase levels of b-adrenergic stimulation of cAMP formation, as would be expected when levels of NE are increased in response to blockade of reuptake or metabolism, sufficient numbers of receptor remain to stimulate cAMP formation in the presence of enhanced synaptic levels of neurotransmitter (see Duman 2004c). Another important concept resulting from this work is that persistent activation in response to chronic, but not acute, antidepressant treatment leads to up-regulation of the cAMP-PKA-CREB cascade. This represents a type of neural plasticity that contributes to the functional actions of antidepressant in animal models of depression and antidepressant response (see below).

Up-regulation of the cAMP-CREB cascade occurs with different classes of antidepressants, including both NE and 5-HT selective reuptake inhibitors (Nestler et al. 1989, Nibuya et al. 1996, Thome et al. 2000, Blom et al. 2002, Laifenfeld et al. 2005). In addition, these effects require chronic antidepressant treatment, consistent with the time course for the therapeutic action of antidepressants. Although it is difficult to determine the therapeutic relevance of these effects, there are several lines of evidence that support the hypothesis that up-regulation of the cAMP-CREB pathway contributes to a therapeutic response, and that disruption of this system could even contribute to depression. First, postmortem studies have found that levels of CREB are decreased in the brains of depressed subjects, and increased in subjects taking antidepressant medication at the time of death (Dowlatshahi et al. 1998, Yamada et al. 2003). Second, rolipram, a drug that activates the cAMP-CREB cascade by blocking the breakdown of cAMP, produces antidepressant effects in human subjects, as well as in animal models. Studies to test the action of the cAMP-CREB cascade in animal models of depression are discussed below as well as the consequences of these findings for drug development.

Functional Consequences of Altered cAMP-CREB Signaling

To determine if up-regulation of cAMP-CREB signaling contributes to the actions of antidepressants, studies have been conducted using viral vectors and mutant mouse models. Viral expression of CREB in the hippocampus, the limbic brain structure where CREB is increased by antidepressant treatment, produces an antidepressant-like effect in the forced swim test (FST) and the learned helplessness (LH) paradigms (Chen et al. 2001a). These are referred to as behavioral despair models of depression that are responsive to antidepressant treatments (see below for discussion of behavioral models). In addition, overexpression of CREB in the amygdala, a region known to control fear and anxiety as well as emotion, also produces an antidepressant response in the LH paradigm in a state dependent fashion (Wallace et al. 2004). That is, when CREB is overexpressed in amygdala...
after exposing animals to inescapable stress an antidepressant effect is observed, but when CREB is expressed before the inescapable stress it enhances the stress response and produces a pro-depressive effect. This is consistent with CREB acting as a mediator of neural plasticity and the ability of amygdala responses to be conditional based on the experiential state of the animal.

Studies of the nucleus accumbens, a target area of the mesolimbic dopamine system that controls motivation and reward, further demonstrate the region specific effects of CREB. Viral over-expression of CREB in this region produces pro-depressive effects in the FST, while expression of a dominant negative mutant of CREB in the nucleus accumbens produces an antidepressant response in the FST and LH paradigm (Pliakas et al. 2001, Newton et al. 2002). Studies of mutant mice carrying a null mutation of CREB exhibit a similar phenotype in the FST (Conti et al. 2002). Taken together, these data demonstrate that altered CREB expression or function influences behavioral models of depression in a region specific manner, consistent with the function of this transcription factor as a prime mediator of neural plasticity in a circuit and state dependent manner (see Carlezon et al. 2005, Blendy 2006).

Up-regulation of CREB indicates that there are target genes of this transcription factor that are regulated and that are directly involved in the function of antidepressants and the cAMP-CREB cascade. Several candidate genes that contain a cAMP response element (CRE), a promoter sequence that CREB binds to, have been examined, most notably the neurotrophic/growth factors BDNF and vascular endothelial growth factor (VEGF). These factors are up-regulated by antidepressant treatment and will be discussed in more detail below in the context of a neurotrophic hypothesis of depression. The induction of these genes demonstrates that antidepressant regulation of the cAMP-CREB cascade has functional consequences on gene transcription that could underlie, in part, the actions of these treatments.

cAMP-CREB Cascade and Novel Therapeutic Agents

These studies raise the possibility of targeting the cAMP-CREB cascade for the treatment of depression and related mood disorders. There are several potential drug targets that can be considered, from receptors that stimulate this second messenger system, to adenylyl cyclase, PKA and CREB. Direct agonists of b-adrenergic or 5-HT receptors provide insufficient evidence to support the choice of one receptor subtype over another. There are very few examples of drugs acting at the level of PKAs or transcription factors. The most interesting and potentially useful strategy is to increase cAMP levels by blocking its degradation via inhibition of cAMP specific phosphodiesterase type IV (PDE4). Previous studies have demonstrated the feasibility of this approach. Rolipram, a selective inhibitor of PDE4, produces an antidepressant response in animal models of depression (Wachtel and Schneider 1986, Griebel et al. 1991, O’Donnell 1993, O’Donnell and Zhang 2004). Moreover, early clinical studies have demonstrated that rolipram administration has antidepressant efficacy in depressed subjects (Horowski and Sastre-Y-Hernandez 1985, Bobon et al. 1988, Fleischhacker et al. 1992). These positive actions of systemic rolipram administration indicates that the prevailing effect in the brain is an antidepressant response, not depressive as was seen in some viral vector and mutant mouse models. However, there was some incidence of nausea in patients receiving rolipram, limiting the clinical utility of this agent.

Molecular cloning studies have renewed the interest in PDE4 as a target for drug development. These studies demonstrate that there are 4 different PDE4 isoforms, three of which are expressed in brain, PDE4A, 4B, and 4D, and all equally sensitive to rolipram. The 3 brain specific isoforms are differentially expressed in limbic structures, suggesting that one or more could mediate the antidepressant effects of rolipram, while another could underlie the unwanted side effects. Recent studies have demonstrated that PDE4A, PDE4B, and PDE4D are up-regulated in animal models and could thereby delay or counter the actions of antidepressants (Takahashi et al. 1999, Ye et al. 2000, D’Sa et al. 2004, Dlaboga et al. 2006). PDE4D is expressed in the area postrema, a region known to control emesis and could contribute to the nausea caused by rolipram (Takahashi et al. 1999). Studies are currently underway to directly test the role of each PDE4 isoform using mutant mice and to develop selective inhibitors of PDE4A, 4B, and 4D. Early studies demonstrate that PDE4D null mutant mice display an antidepressant profile in the FST, suggesting that this subtype could be involved in the actions of rolipram (Zhang et al. 2004). Further studies of PDE4A and PDE4B in this and other behavioral models will be needed to further identify the most important isoform target for the treatment of depression.

Growth/Neurotrophic Factors in Depression and Antidepressant Actions

Several lines of evidence have contributed to a neurotrophic hypothesis of depression and antidepressant response, including data from basic and clinical studies. A brief review of neurotrophic/growth factor systems and signaling pathways will be discussed, followed by an overview of the data demonstrating the role of these factors in the pathophysiology and treatment of depression (Duman 2004a, Duman and Monteggia 2006).

Neurotrophic/Growth Factor Systems

The nerve growth factor (NGF) family has been the focus of stress, depression and antidepressant studies, although recent work has also demonstrated a role for other growth factor systems, most notably insulin like growth factor-1 (IGF-1), fibroblast growth factor-2 (FGF-2), and VEGF. The NGF family includes NGF, BDNF, neurotrophin-3 (NT-3) and neurotrophin-4 (NT-4). These factors were originally identified for their role in the development and survival of neurons, but it is now clear that members of the NGF family are expressed in the adult brain and continue to influence neuronal survival and protection, as well as many aspects of neuronal function, including neural plasticity and adult neurogenesis. IGF-1, VEGF, and FGF-2 are also differentially expressed in the adult brain and exert effects that overlap with NGF family members, as well as other functions.

Neurotrophic/Growth Factor Signaling Cascades

The receptors for BDNF and other NGF family members have an extracellular binding domain and intracellular
tyrosine kinase domain. There are three receptors, TrkA, TrkB, and TrkC that bind with selectivity to NGF, BDNF, and NT-3/NT-4, respectively, although NT-3 can also bind to TrkB. Binding of a neurotrophic factor dimer to a receptor dimer is required for functional activation of the tyrosine kinase domain, leading to autophosphorylation and activation of multiple signal pathways. This includes the MAP or ERK kinase cascade, phosphatidylinositol-3 kinase (PI-3K) and phospholipase Cg (PL-Cg). These pathways are activated by phosphorylation of or interaction with coupling proteins that link with effector/catalytic components of each. For the MAP kinase pathway, this includes phosphorylation of the adaptor protein Shc, which then couples with another adaptor protein Grb2, which in turn recruits the guanine nucleotide exchange protein Sos. This leads to loading of the membrane bound GTPase, Ras, which then recruits and activates Raf, the first kinase in the MAP pathway. Raf activates MEK that in turn phosphorylates and activates ERK. This leads to translocation of ERK to the nucleus where it regulates a number of transcription factors. ERK can also phosphorylate and activate RSK family kinases that can activate CREB.

Trk receptors also recruit and activate PI-3K via Shc and Grb2, leading to the activation of AKT, which has anti-apoptotic actions. Trk receptors directly phosphorylate and activate PLCg, leading to regulation of Ca2+ and PKA signaling pathways. All three of these pathways (MAP kinase, PI-3K, and PLCg) also serve as the major signaling cascades for other trophic factors implicated in depression (i.e., IGF-1, FGF-2, and VEGF).

Atrophy and Cell Loss: Decreased Growth Factor Expression

Evidence from basic and clinical research studies have provided evidence of neuronal atrophy and cell loss in depression, supporting the possibility of altered neurotrophic and growth factor support in mood disorders. Basic research studies demonstrate that repeated stress causes atrophy of pyramidal neurons in the hippocampus and prefrontal cortex, characterized by a decrease in the number and length of apical dendrites (Wooley et al. 1990, Watanabe et al. 1992, Radley et al. 2004, McGowan 2005). Studies in rodent models have also demonstrated that stress decreases the proliferation of new neurons in the adult hippocampus and the number of glia in the adult prefrontal cortex (Gould et al. 1997, 1998, Czeh et al. 2001, Duman 2004b, Banasr et al. 2007). Decreased number of glia and size of neurons has also been reported in postmortem studies of depressed subjects (Ongur et al. 1998, Rajkowska et al. 1999, Cotter et al. 2001). This type of atrophy and cell loss could underlie the reduction in volume that is reported in the hippocampus and prefrontal cortex of depressed subjects (Bremner et al. 1995, Drevets et al. 1997, Sheline et al. 1999, 2001).

While the mechanisms underlying neuronal atrophy and cell loss are not fully determined, decreased neurotrophic factor support could play a role. Different types of acute and chronic stress, as well as physical, social and emotional stress decrease the expression of BDNF in the hippocampus and prefrontal cortex (Smith et al. 1995, Duman and Monteggia 2006). Other neurotrophic/growth factors are decreased by stress, including reduced levels of NGF (Ueyama et al. 1997) and VEGF (Heine et al. 2005).

Antidepressant Treatment Increases Neurotrophic Factor Expression

In contrast to the effects of stress, antidepressant administration increases the expression of neurotrophic factors in limbic brain regions. Increased BDNF expression is observed with administration of different classes of antidepressants, including 5-HT and NE reuptake inhibitors, MAOIs, atypical antidepressants, and electroconvulsive therapy (ECT) (Nibuya et al. 1995, Nibuya et al. 1996, Duman and Monteggia 2006). It is notable that other treatments with antidepressant efficacy, also increase the expression of BDNF, including exercise, transcranial magnetic stimulation, AMPAkines, and NMDA receptor antagonists (see Duman and Monteggia 2006). Antidepressant treatment reverses the decrease observed with stress in animal models (Nibuya et al. 1995) and in postmortem brains of depressed subjects (Chen et al. 2001b). The actions of chemical antidepressants require repeated treatment, consistent with the time course for the therapeutic action of these agents. There are also negative reports, that antidepressant treatment does not increase the expression of BDNF, possibly due to uncontrolled (e.g., stress, activity) as well as controlled variables (e.g., dose, treatment time) (see Duman and Monteggia 2006). The regulation of ERK by chemical antidepressants has also been variable (Tiraboschi et al. 2004, Fumagalli et al. 2005), and additional studies will be needed to further characterize the regulation of this and other trophic factor signaling cascades by antidepressants.

In addition to BDNF, there are several other growth factors that are reported to be up-regulated by chronic antidepressant treatment, including VEGF (Newton et al. 2003, Warner-Schmidt and Duman 2007), IGF-1 (Khadaji et al. 2004), and FGF-2 (Malle et al. 2002). A postmortem microarray study has also found that the expression of FGF-2 is decreased in the brains of depressed subjects (Evans et al. 2004). The role of these factors in the neurogenic and behavioral actions of antidepressants is discussed in more detail below.

Functional Consequences of Altered Neurotrophic Factors

To determine if the expression of BDNF in specific brain structures leads to functional effects related to the actions of stress and antidepressants, recombinant proteins and mutant mouse models have been tested. Infusions of BDNF into the midbrain, hippocampus, or lateral ventricles produce an antidepressant effect in behavioral models of depression and
antidepressant response, including the FST and LH paradigms (Siciak et al. 1997, Shirayama et al. 2002, Hoshaw et al. 2005). Chemical inhibitors of the MAP-kinase cascade block these effects of BDNF (Shirayama et al. 2002), and also block the actions of antidepressant treatment (Duman et al. 2006). Infusions of either of other trophic factors, including VEGF (Warner-Schmidt and Duman 2007) or IGF-1 (Hoshaw et al. 2005) also produce antidepressant effects in behavioral models. Studies of BDNF mutant mice also demonstrate that the actions of antidepressants are dependent on an intact BDNF system (Saarelainen et al. 2003, Monteggia et al. 2004). Similar effects have been observed in mice that express a dominant negative form of the BDNF receptor, TrkB (Saarelainen et al. 2003). However, it should also be noted that BDNF in the mesolimbic dopamine system is required for behavioral responses in a social defeat model (Berton and Nestler 2006).

Partial or complete deletion of BDNF or TrkB does not lead to a depressive phenotype in mouse models, indicating that loss of BDNF alone is not sufficient to produce a depressive response (MacQueen et al. 2001, Zorner et al. 2003, Chourbaji et al. 2004). However, when mice with a partial deletion of BDNF are exposed to stress a depressive phenotype is observed (Duman et al. 2006). A similar genotype x environment effect has been demonstrated for the short (S) allele of the 5-HT transporter in humans exposed to early life stress or trauma (Caspi et al. 2003) (see below), and a recent study has demonstrated that individuals carrying a met allele at position 66 of BDNF instead of a val allele, combined with the 5-HT S allele are susceptible to depression when exposed to early life trauma (Kaufman et al. 2006) (see below). This type of genetic disposition explains, in part, why certain individuals are vulnerable to stress exposure, while others experience stress but do not become depressed.

**Neurogenesis in the Adult Hippocampus**

Despite earlier work, it is now clear that new neurons continue to be added to two specific regions of the brain, the hippocampus and olfactory bulbs, in adult animals and even in old age (Gould and Tanapat 1999, Gage 2000). New cell birth has been reported in a variety of animals, including birds, rodents, nonhuman primates, and in humans using brdu labeled brain tissue obtained postmortem from cancer patients (Eriksson et al. 1998). Moreover, the rate of new cell birth is influenced by a variety of stimuli, including those that increase it (e.g., antidepressants) and those that decrease it (stress, aging, drugs of abuse), suggesting that neurogenesis is a type of neural plasticity with consequences for neuronal function and behavior. Although studies to determine the functional significance of adult neurogenesis are technically demanding, some of the most convincing work has been done with respect to models of depression and antidepressant action.

### Opposing Actions of Stress and Antidepressant Treatment

These studies demonstrate that stress exposure decreases the proliferation of newborn neurons in the adult hippocampus of rodents and nonhuman primates (Gould et al. 1997, 1998, Czeh et al. 2001, Duman 2004b). Decreased neurogenesis is observed in response to different types of stress, including social subordination, predator odor, restraint, and chronic mild stress. In addition, administration of the adrenal-glucocorticoid that is active in rodents, corticosterone, decreases neurogenesis, indicating the actions of stress could occur via this stress-responsive steroid (Cameron et al. 1998).

In contrast, chronic antidepressant administration increases the proliferation of new neurons in the adult hippocampus. Increased neurogenesis is observed with different types of antidepressants, including 5-HT and NE selective reuptake inhibitors, MAOIs, rolipram, ECT, and exercise (van Praag et al. 1999, Madsen et al. 2000, Malberg et al. 2000, Nakagawa et al. 2002, Santarelli et al. 2003, Duman 2004). The actions of antidepressant treatment require chronic administration, consistent with the time course for the therapeutic effects of antidepressants. In addition to increased neurogenesis in naïve animals, antidepressant administration also blocks the down-regulation of new cell birth that is caused by stress (Czeh et al. 2001, Malberg and Duman 2003, Alonso et al. 2004). Antidepressant administration increases the rate of cell proliferation, as well as the survival of newborn cells, and increases the number of mature neurons in the granule cell layer of the hippocampus (Malberg et al. 2000, Nakagawa et al. 2002).

### Functional Consequences of Altered Neurogenesis

The opposing actions of stress and antidepressants raise a question regarding the functional relevance of adult neurogenesis. At the very least, the consistent reports that stress decreases and that different classes of antidepressants increase adult neurogenesis indicate that this is a reliable marker of responses to these treatments. Indeed, increased neurogenesis is being used to test for novel antidepressant medications. It has been difficult to determine the functional significance of newborn neurons, because approaches to block cell proliferation specifically in the hippocampus have been technically difficult and limited.

However, significant progress has been made using a variety of approaches. In a landmark paper, Rene Hen’s laboratory demonstrated that blocking antidepressant induction of adult neurogenesis, by either irradiation or in a mutant mouse model, completely blocked the actions of antidepressants in two behavioral models (Santarelli et al. 2003). Focused irradiation of the hippocampus kills dividing cells and thereby blocks cell proliferation; a null mutation of the 5-HT1A receptor blocks the induction of neurogenesis by SSRI antidepressants. When these animals were treated with an antidepressant, the expected behavioral responses in the novelty suppressed feeding and chronic unpredictable stress paradigms were completely blocked. Both of these models require chronic antidepressant treatment, consistent with the time frame required for differentiation and maturation of newborn neurons. However, the reduction in neurogenesis caused by irradiation alone did not cause a depressive phenotype in these models. Taken together the data demonstrate that induction of neurogenesis in the adult hippocampus is required for the behavioral actions of antidepressants, but that decreased neurogenesis alone is not sufficient to produce depression. Studies are currently underway in a number of laboratories to further test this hypothesis using transgenic mice that express cell cycle inhibitors in neural progenitor cells.
Mechanisms Underlying Actions of Stress and Antidepressants

There has been some progress in identifying the mechanisms underlying the regulation of adult neurogenesis by stress and antidepressants. Administration of corticosterone also decreases neurogenesis, and this effect can be blocked by administration of an NMDA receptor antagonist (Cameron et al. 1998). In addition, recent studies demonstrate that infusion of an interleukin-1β antagonist blocks the down-regulation of adult neurogenesis caused by acute stress (Koo and Duman, personal communication). These studies demonstrate a complex interaction between adrenal steroids, glutamate neurotransmission, and cytokines in the actions of stress.

Studies of antidepressants have focused on the cAMP-CREB cascade and neurotrophic/growth factors. Activation of the cAMP-CREB cascade by rolipram increases adult neurogenesis, and up-regulation of this pathway could contribute to the actions of antidepressant treatment (Nakagawa et al. 2002). Studies of BDNF demonstrate that this neurotrophic factor plays a role in the survival, but not proliferation of newborn neurons resulting from antidepressant administration (Saarien et al. 2005). A recent report demonstrates that VEGF plays an essential role in antidepressant induction of neurogenesis (Warner-Schmidt and Duman 2007). Blockade of VEGF signaling blocks the induction of neurogenesis by different types of antidepressants, including 5-HT and NE reuptake inhibitors and ECT, and infusion of VEGF is sufficient to increase neurogenesis. In addition, this study demonstrated that blockade of VEGF signaling blocks the actions of antidepressants in both short-term models that require neurogenesis (i.e., novelty suppressed feeding and chronic unpredictable stress) as well as short-term models (i.e., FST and LH). These studies demonstrate that VEGF is an important mediator of the neurogenic actions, but indicate that VEGF also leads to more rapid effects, possibly at the level of synaptic activity and/or neural plasticity.

Conclusion

The causes and mechanisms of mood disorders are beginning to be investigated at multiple levels of analysis. Research in humans and animal models is clarifying the roles of altered neuromodulator and neuroendocrine systems, and discovering the involvement of intracellular signaling cascades, nerve growth factors, and risk genes and their interactions with specific adverse environments, in the pathogenesis of unipolar and bipolar disorders. Susceptibility genes for bipolar disorder or unipolar depression are believed to include: (1) regulators of neurotransmitter function including glutamic acid decarboxylase 1, monoamine oxidase A, catechol-O-methyl transferase, and the serotonin transporter, (2) regulators and participants in intracellular signaling including phosphodiesterase 11A and brain-derived nerve growth factor, and (3) components of the hypothalamic pituitary adrenal axis including the glucocorticoid receptor. The early putative mechanisms involving neuromodulator and neuroendocrine dysregulation have been extended and linked to the roles of intracellular cAMP-CREB and nerve growth factor family signaling cascades as well as hippocampal neurogenesis. These insights are leading to new hypotheses for candidate therapies.

Clinical Picture

What is Addiction?
Drug addiction, also referred to diagnostically as substance dependence (American Psychiatric Association 2000), is a chronically relapsing brain disorder characterized by: (1) compulsion to seek and take a given drug; (2) loss of control in limiting intake; and (3) emergence of a negative emotional state (e.g., dysphoria, anxiety, irritability) when the drug is unavailable or access to it is prevented (Koob and Le Moal 1997).

We will also use addiction and substance dependence interchangeably throughout this text. Drug addiction is a chronic relapsing disorder (Meyer 1996), defined by presenting symptoms, etiology, and pathophysiology that moves from drug experimentation to abuse to addiction. The associated medical, social, and occupational difficulties that usually develop during the course of addiction do not disappear after detoxification because addictive drugs are thought to produce changes in brain pathways that endure long after the person stops taking them. These protracted brain changes and the associated personal and social difficulties put the detoxified patient at risk of relapse (O'Brien and McLellan 1996), a risk higher than 60% within the year that follows discharge (Finney and Moos 1992, Hubbard et al. 1997, McLellan and McKay 1998, McLellan et al. 2000). While much of the initial study of the neurobiology of drug addiction focused on the acute impact of drugs of abuse (comparing no drug use to drug use), the focus now is shifting to the study of chronic administration and the acute and long-term neuroadaptive changes in the brain that result in relapse. Cogent arguments have been made supporting the idea that addictions are similar in their chronic relapsing properties and limited efficacy of treatment to other chronic relapsing disorders such as diabetes, asthma, and hypertension (McLellan et al. 2000). The purpose of current neurobiologic drug abuse research is to understand the cellular and molecular mechanisms that mediate the transition from occasional, controlled drug use, to the loss of behavioral control over drug-seeking and drug-taking, and chronic addiction (Koob and Le Moal 1997).

The diagnostic criteria for substance use disorders, as specified by the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association 2000), cover two maladaptive patterns of substance use: (1) substance abuse and (2) substance dependence (addiction). Abuse is less severe than dependence and is diagnosed only if criteria for dependence are not met. The criteria for dependence have evolved over the past 30 years with a shift of emphasis from the necessary physiological criteria of tolerance and withdrawal to behavioral criteria for compulsive use. Tolerance and withdrawal form two of the seven potential criteria that need to be experienced within a 12-month period. The criteria for substance dependence outlined in the DSM-IV-TR closely resemble those outlined by the International Statistical Classification of Diseases and Related Health Problems (ICD-10) (World Health Organization 1992) (Table 22–1). In both systems, the specific withdrawal symptoms vary across drugs. As noted by Hughes (2006), generic criteria are based in part on shared genotype across different drugs, common underlying neurobiological processes, as well as by common behavioral correlates, such as antisocial syndromes (Compton et al. 2005a, Nelson et al. 1999). However, the assumption on which these criteria are based has been challenged, especially

regarding nicotine dependence (Hughes 2006), and needs better empirical validation. Indeed, the number of criteria met by dependent users varies with the drug in question, the severity of the addiction, the stage of the addiction process, and the age of the user (Chung and Martin 2001). For instance, for alcohol, marijuana, cocaine, and heroin, the two most frequently mentioned criteria are tolerance (criterion #1) and time spent using, procuring the drug (criterion #5). Withdrawal (criterion #2) is mentioned much more frequently with respect to heroin than cocaine, and more frequently with respect to alcohol than cocaine, based on the National Survey on Drug Use and Health (NSDUH) 2005 (Substance Abuse and Mental Health Services Administration 2006). The DSM-IV-TR does not include withdrawal from cannabis as a criterion even though a cannabis withdrawal syndrome is now well-established (Budney et al. 2003).

Abuse is diagnosed if the person has not been diagnosed as being dependent, but engages in recurrent substance use during a 12-month period resulting in at least one of the four harmful consequences, including failure to fulfill major role obligations, hazardous use, legal problems, and continued use despite social or interpersonal problems caused by the substance (Table 22–2). Dependence has multiple meanings. Particularly confusing has been the use of “physical dependence,” which refers to the adaptations that occur with repeated exposure to drugs and that upon discontinuation result in symptoms of withdrawal that can be mild (such as mild fatigue with cocaine) or severe (vomiting, seizures with alcohol and heroin) and which are distinct from the adaptations that result in addiction. The changes and symptoms associated with physical dependence develop and resolve much faster than...
the symptoms associated with “addiction.” Thus, an individual can become physically dependent on a drug without being addicted, and an individual can be addicted without suffering from physical dependence. Meeting the DSM-IV-TR criteria for substance dependence is much more than a manifestation of a withdrawal syndrome (physical dependence); rather it reflects an addictive state. In this chapter, we will refer to substance dependence as defined by the DSM-IV-TR. Substance dependence, addiction, and alcoholism will be held equivalent.

**Stages of the Addiction Cycle**

From a psychiatric perspective, drug addiction has aspects of both impulse control and compulsive disorders. Impulse control disorders are characterized by three factors: (1) an increasing sense of tension or arousal before committing an impulsive act; (2) pleasure, gratification, or relief at the time of committing the act; and (3) regret, self-reproach, or guilt following the act (American Psychiatric Association 1994). In contrast, compulsive disorders are characterized by two factors: (1) anxiety and stress before committing a compulsive repetitive behavior; and 2) relief from the stress by performing the compulsive behavior. As an individual moves from an impulsive disorder to a mixed compulsive/impulsive disorder, there is a shift from positive to negative reinforcement driving the motivated behavior and increasing control by automated prepotent responses (Koob 2004) (Figure 22–1). As these arguments illustrate, drug addiction can best be conceptualized as a disorder that progresses from impulsivity to compulsivity in a cycle comprised of three stages: preoccupation/anticipation, binge/intoxication, and withdrawal/negative affect. (Koob and Le Moal 1997) (Figure 22–2).

![Figure 22–1 Diagram showing stages of impulse control disorder and compulsive disorder cycles related to the sources of reinforcement. In impulse control disorders, an increasing tension and arousal occurs before the impulsive act, with pleasure, gratification, or relief during the act. Following the act, there may or may not be regret or guilt. In compulsive disorders, there are recurrent and persistent thoughts (obsessions) that cause marked anxiety and stress followed by repetitive behaviors (compulsions) that are aimed at preventing or reducing distress (American Psychiatric Association 1994). Positive reinforcement (pleasure/gratification) is more closely associated with impulse control disorders. Negative reinforcement (relief of anxiety or relief of stress) is more closely associated with compulsive disorders. (Taken with permission from Koob 2004.)](image-url)

Patterns of Addiction

Different drugs produce different patterns of addiction with emphasis on different components of the addiction cycle. Opioids are probably the classic drug of addiction. A pattern of drug-taking evolves, including an intense intoxication via the intravenous or smoking routes for heroin and oral or intravenous administration for opioid analgesics, the development of tolerance, escalation in intake and profound dysphoria, physical discomfort and somatic withdrawal signs during abstinence. Intense preoccupation with obtaining opioids (craving) develops that often precedes the somatic signs of withdrawal, and this preoccupation is linked not only to stimuli associated with obtaining the drug but also to stimuli associated with withdrawal and internal and external states of stress. The drug must be obtained to avoid the severe dysphoria and discomfort during abstinence.

Addiction to alcohol follows a similar pattern, but the intoxication is less intense and the pattern of drug-taking is often characterized by binges of alcohol intake that can consist of daily episodes or prolonged days of heavy drinking. A binge is defined as five standard drinks for males and four standard drinks for females in a 2 h period or a blood alcohol level of 0.08%. Addiction to alcohol is characterized by a severe emotional and somatic withdrawal syndrome and intense craving for the drug that is often driven by negative emotional states, positive emotional states, and environmentally conditioned stimuli (stimuli that have been associated with drinking). Many alcoholics continue with such a binge/withdrawal pattern for extended periods, but some evolve into an opioid-like situation where they must have alcohol available at all times to avoid the consequences of abstinence.

Nicotine addiction contrasts with the above patterns in that nicotine has less of a binge/intoxication stage. Cigarette smokers who meet the criteria for substance dependence are likely to smoke throughout the waking hours and to experience negative emotional states with dysphoria, irritability, and intense craving during abstinence. The binge/intoxication stage forms a minor component of nicotine dependence where the pattern is highly titrated intake of the drug that does not interrupt daily activity and that is maintained throughout the day only to be interrupted during periods of sleep. Psychostimulants such as cocaine and amphetamines show a pattern that emphasizes the binge/intoxication stage. Such binges can last for hours or days and are often followed by a crash characterized by dysphoria, fatigue, and inactivity. Intense craving follows later, and is driven both
Development of Addiction: Self-Regulation and Self-Medication

Failure of self-regulation is thought to be at the root of major social pathologies and a key element in the development of addiction (Baumeister et al. 1994). Important self-regulation elements may be involved in the different stages of addiction as well as in other pathological behaviors such as compulsive gambling and binge eating. Self-regulation failures set up future failures to self-regulate, and ultimately lead to the chronic relapsing disorder considered as addiction (Baumeister et al. 1994).

From a self-medication perspective, two critical elements (disordered emotions and disordered self-care) and two contributory elements (disordered self-esteem and disordered relationships) have been identified and incorporated into a self-medication hypothesis. Here, individuals with substance use disorders are thought to take drugs as a “means to cope with painful and threatening emotions.” In this conceptualization, addicted individuals experience states of subjective distress and suffering that may or may not be associated with conditions meeting the DSM-IV-TR criteria for a psychiatric diagnosis (American Psychiatric Association 1994).

Self-medication may be drug-specific in that individuals may prefer to use drugs that fit with the nature of the painful affective states that they are attempting to alleviate. For example, certain individuals may find that opiates are effective in reducing psychopathological states of violent anger and rageful feelings. Others, suffering from anhedonia,nergia, or lack of feelings, will prefer the activating properties of psychostimulants. Some individuals who are flooded in their feelings, or cut off from feelings, will welcome repeated moderate doses of alcohol or antidepressants to express feelings that they are not able to communicate. Thus, in some cases, the operative motive is to relieve painful feelings; in others, it is to control or express feelings (Khantzian, 1995, 1997, Khantzian and Wilson 1993). According to this view, each class of drugs can, in principle, serve as a specific antidote to specific dysphoric states and act as a “replacement for a defect in the psychological structure” of the individuals (Kohut 1971). The paradox of addiction, of course, is that by choosing drugs to self-medicate emotional pain, the drugs themselves will perpetuate it, by perpetuating a life revolving around drugs.

This psychodynamic approach integrates well with growing evidence for a critical role of dysregulated brain reward and stress systems in drug addiction from studies on the neurobiology of addiction using animal models (see sections that follow). However, from a neurobiological perspective, there is an additional insult to personality produced by the direct effects of the drugs themselves that perpetuate, and actually create, such character flaws (Koob 2003).

Patterns of Substance Use and Substance Use Disorders

Overall Prevalence

Modern epidemiological studies have distinguished three clinical patterns of drug use: (1) occasional, controlled or social use; (2) drug abuse and/or harmful use; and (3) drug dependence/addiction. A large number of individuals in the population engage in each of these behaviors. Four national surveys implemented since 2001 have measured substance use and substance use disorders in the US population: the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) (Grant et al. 2004c, Compton et al. 2005a, Conway et al. 2006), the National Comorbidity Survey Replication (NCS-R) (Kessler et al. 2005a, b), the NSDUH (Substance Abuse and Mental Health Services Administration, 2006), and the annual Monitoring the Future, which focuses on adolescents. (Johnston et al. 2007) These surveys have different strengths and weaknesses and generate somewhat different estimates of rates of substance use and substance use disorders (Compton et al. 2005a, Cottler 2007, Grant et al. 2007, Grucza et al. 2007, Kessler and Merikangas 2007). Prevalences based on the 2005 NSDUH are displayed in Table 22–3. In 2005, 46% (112 million) of the US population of 12 years or older were engaged in nonmedical or illicit drug use at some time in their lives. Of these, approximately 2.8% (6.8 million) experienced a DSM-IV-TR substance use disorder of an illicit drug in the last year, 0.9% experienced abuse, and 1.9% experienced dependence (SAMHSA 2006: Tables G.1, G.2, G.29, G.30; secondary analyses).

Eighty-three percent (202 million) of persons aged 12 years and over had ever drank alcohol, while 52% (126 million) had consumed alcohol within the last month (SAMHSA 2006: Table G.16). Of those who drank in the last year, 11% (18.6 million) met the criteria for DSM-IV-TR substance abuse or dependence on alcohol (SAMHSA 2006: Tables G.29, G.30). All said, 22.2 million Americans, 9% of the population aged 12 and older, experienced abuse or dependence on alcohol or an illicit drug within the prior 12 months; the same proportion did so among those aged 18 and older. This compares to 12-month prevalence of 9% for mood disorders or 11% for anxiety disorders in the population aged 18 and older (Grant et al. 2004b). In addition, 66% (161 million) of those aged 12 and over who had ever smoked cigarettes, and 35% (25.1 million) of those who smoked in the last year met the criteria for nicotine dependence in the last 30 days, as measured by the Nicotine Dependence Symptom Scale (NDSS) (Shiffman et al. 2004).
The proportion of individuals meeting the criteria for abuse or substance dependence on a given drug among those who used the drug varies greatly across drug classes. In 2005, the percentage of last year users with a substance use disorder was the highest for heroin, followed by cigarettes (nicotine) and cocaine (Table 22–3 and Figure 22–3). The percentages for the other drugs were much lower. The proportion of individuals with an alcohol-related disorder among those who consumed alcohol in the last year was among the lowest of any of the substances. However, because so many individuals consume alcohol, this percentage translates into a large number of affected individuals.

Considering all drugs in aggregate in 2005, only 12% of the population aged 12 and over had not experimented with any substance; 41% had experimented with all three major classes: alcohol, tobacco, and illicit drugs (based on 2005 NSDUH). Similarly, multiple substance use disorders tend to co-occur. In 2001–2002, 40% of individuals aged 18 and over in the population who met the criteria for abuse or dependence on one drug class also met the criteria for abuse or dependence on at least another drug; 12% met the criteria for abuse or dependence on two other substances. The highest comorbidity was between dependence on an illicit drug and dependence on alcohol or nicotine. 70% of those dependent on an illicit drug also were dependent on alcohol, and 69% were dependent on nicotine (secondary analysis of 2005 NESARC). Yet, only a minority of addicted individuals have been treated for their addiction (Compton et al. 2007).

Table 22–3 Estimated Lifetime and Last Year Prevalence of Nonmedical Substance Use, Substance Abuse, and Substance Dependence among all Persons Aged 12 and over

* Only dependence on cigarettes was ascertained.
† Source: NHS03710, 3713, 3718, 3733, 3743, 3744.
Source: Based on secondary analysis of the 2005 National Survey on Drug Use and Health (Substance Abuse and Mental Health Services Administration, 2006).

Figure 22–3 Rates of DSM-IV-TR substance use disorders among last year users 12+ years old (based on the 2005 NSDUH; Substance Abuse and Mental Health Services Administration 2006).
Devotional Stages of Involvement in Drugs

Not only are there regular patterns of co-occurrence of use, abuse, and dependence across drugs, but also there are regular sequences of progression from the use of one drug class to another. The existence of a developmental sequence of involvement in drugs is one of the best replicated findings in the epidemiology of drug use (Kandel 2002). Both in the United States and in other Western societies, a regular sequence and stages of progression have consistently been found. In this sequence, the use of cigarettes (nicotine) or alcohol precedes the use of marijuana (cannabis) and, in turn, the use of marijuana precedes the use of other illicit drugs. Very few individuals who have tried cocaine and heroin have not previously used marijuana, and the majority have used alcohol or cigarettes prior to their use of marijuana. Such behavioral regularities have given rise to the Gateway Hypothesis. However, in the 30 years since publication of the original observation (Kandel and Faust 1975), surprisingly, little progress has been made in addressing three fundamental questions that derive from the observation that the use of one class of drug is followed by the use of another class. We still do not know: (1) whether the use of the first class of drugs, such as nicotine, is a cause of the use of the second class, such as cocaine, or whether the sequence is determined exclusively by availability of the drug or other social factors; (2) what biological mechanisms underlie this progression in drug use; and (3) why early use during adolescence leads to more extensive and chronic use than later onset of drug use postadolescence. Ongoing work on animal models will help answer these questions.

Prevalence Rates by Age, Gender, Race/Ethnicity

There are important differences in the prevalence of use and substance use disorders in different subgroups in the population.

Age

Age differences in patterns of substance use are the most pronounced, and this is particularly evident in the use of illicit drugs. The highest rates of substance use occur among young adults 18–24 years old. At age 25, the rates for cigarettes and illicit drugs begin to decline steeply; whereas the rates for alcohol do not begin to decline until age 50 (Figure 22–4). Among users, the age-related patterns for dependence differ across drugs. For alcohol and illicit drugs, the rates of dependence among last year users peak at age 18–24 and decline gradually whereas for cigarettes they climb steadily through age 35–49, when they stabilize.

Gender

Gender patterns for substance use differ from those for substance use disorders. For all substances, including the nonmedical use of psychotherapeutic drugs, males have consistently higher prevalences of use than females (Table 22–3). Among drug users, however, males have higher rates than females for alcohol, cannabis, inhalants, and tranquilizers; for all other drug classes, the rates of disorders among users are the same or higher among females. With regard to dependence specifically, the conditional rate of alcohol dependence is 60% higher among males than females; the rates of dependence on cocaine, stimulants, sedatives, and heroin are 40–90% higher among females than males.

Race/Ethnicity

There are striking race/ethnic differences in patterns of substance use and substance disorders in the population (Table 22–4). With the exception of heroin, the lifetime prevalence of use for each drug class is higher among non-Hispanic whites than non-Hispanic African-Americans or Hispanics, and especially Asians, who have the lowest rates of use of any group. However, the differences in rates of use between non-Hispanic whites and African-Americans reverse by the age of mid-30s (Kandel 2006). By contrast, except for cigarettes, analgesics, and tranquilizers, the rates of substance use disorders among users of each substance, and particularly dependence, are consistently higher among Non-Hispanic African-Americans than any other group; the rates are generally lowest among Asians.

Impact of Substance Use Disorders

Medical Consequences

Substance abuse and addiction contribute to various medical disorders, including pulmonary and cardiovascular disease, stroke, cancer, infectious diseases (HIV and hepatitis C), and mental disorders (i.e., anxiety disorder, depression, psychoses). Smoking is considered the number one preventable cause for morbidity and mortality worldwide. It is estimated that tobacco is responsible for five million deaths worldwide each year (Ezzati and Lopez 2003), a figure expected to rise to ten million deaths annually by 2020 (World Health Organization 1999). Though the most frequently recognized causal association is that between tobacco smoking and lung cancer, smoking also contributes to cancers of the mouth, throat, larynx, blood, stomach, pancreas, kidney, bladder, cervix. Smoking also contributes to a wide variety of pulmonary diseases, most notably chronic obstructive pulmonary diseases and asthma.

The medical consequences of the use of drugs depend on their pharmacological effects, routes of administration,
duration of use, and stage in a subject’s life at which they are consumed. For example, alcohol is a recognized teratogen, and its use during pregnancy is associated with severe adverse developmental consequences to the offspring, including facial dysmorphism, growth retardation, and mental retardation. In addition, heavy drinking associated with thiamine deficiency can lead to Wernicke’s Korsakoff syndrome (Day et al. 2004) characterized by neurological effects that can trigger ischemia to the nervous tissue. Thus, any mechanism of neurotoxicity results from vascular transmission of HIV/AIDS, hepatitis B and C, and other sexually transmitted diseases.

Brain damage depends on the class of drug. A common mechanism of neurotoxicity results from vascular effects that can trigger ischemia to the nervous tissue. Thus, strokes have been associated with consumption of a wide variety of drugs, including cocaine, alcohol, methamphetamine, and nicotine. In addition, certain drugs target specific cell types such as serotonin neurons by ecstasy or dopamine cells by methamphetamine. Inhalants also have been linked with unique neurotoxic effects that target white matter tissue and peripheral nerves.

**Psychiatric Comorbidity**

There is extensive comorbidity between addiction and mental illness, documented most recently by NESARC (Compton et al. 2005b, Conway et al. 2006, Grant et al. 2004b, c, d, Hasin et al. 2005). Psychiatric comorbidity is especially high for drug dependence on an illicit drug. In 2001–2002, 41% of individuals with a drug use disorder (abuse or dependence) had a mood disorder and 30% an anxiety disorder. Among those with dependence specifically, the rates were 50% higher, i.e., 62% and 47%, respectively (Conway et al. 2006). The associations between psychiatric disorders and substance dependence (as measured by odds ratios) are highly statistically significant for all substances.
and all classes of psychiatric disorders (Table 22–5). The associations are somewhat higher for mood than anxiety disorders, and much higher—by a factor of two or three—for antisocial personality than mood or anxiety disorders. However, psychiatric comorbidity is almost the same with dependence on alcohol and nicotine, and lower for these two legal drugs and inhalants than for the remaining seven classes of illicit drugs that were considered. The associations between psychiatric disorders and dependence on the seven classes of illicit drugs are all extremely high, and lower for the legal drugs alcohol and nicotine, and for inhalants. In general, the substances with the lowest prevalences of dependence in the population have the highest rates of comorbidity with psychiatric disorders (Compton et al. 2005a, Conway et al. 2006). There are associations between specific disorders and specific drugs (Conway et al. 2006; Tables 4 and 5).

A particularly strong comorbidity exists between schizophrenia and nicotine use and dependence. Rates of smoking may be three to four times higher among schizophrenics than in the general population and higher than among individuals diagnosed with other psychiatric disorders (Dallack et al. 1998, Kumari and Postma 2005). This association may represent self-medication for the cognitive and negative symptoms prominent in schizophrenia, given the interaction of nicotine with dopaminergic and glutamatergic transmitter systems (Dallack et al. 1998, Kumari and Postma 2005).

As suggested by Compton et al. (2005a), the strong association with antisocial disorders across various substances suggests that there is an underlying comorbidity factor rather than substance-specific links. This has important implications regarding the potential commonality of selected mechanisms and genetic factors underlying substance use disorders and psychiatric disorders, especially antisocial personality disorders. Although rates of psychiatric disorders vary substantially across racial/ethnic groups, the association between alcohol dependence and drug dependence on illicit drugs with mood and anxiety disorders is similar among whites, African-Americans, Hispanics, and Asians, but not Native Americans (Smith et al. 2006).

These cross-sectional associations do not elucidate developmental processes underlying comorbidity, whether the mental illness was followed by drug dependence or whether drug dependence was followed by mental illness. For some cases, mental illness and addiction may co-occur independently (Grant et al. 2004a). For others, there might be a sequential relationship. The direction of causality between psychiatric disorders and dependence is ambiguous because both pathways of influence have been documented. For instance, among adolescents and young adults, depression and social anxiety predict the onset of smoking and nicotine dependence (Breslau et al. 2004, Karp et al. 2006, Kessler 2004), but prior smoking and nicotine dependence also predict depression, disruptive disorders, panic attacks and disorder, and agoraphobia (Breslau and Klein 1999, Breslau et al. 2004, Glassman 1993, Klungsøyr et al. 2006). The association between depression and smoking is probably reciprocal (Breslau et al. 1998), and may be determined by shared genetic or environmental factors. It is likely that different neurobiological factors are involved in comorbidity depending on its developmental course. When mental illness is followed by dependence on some types of drugs, comorbidity might reflect self-medication, as discussed earlier. However, when drug dependence is followed by mental illness it is possible that chronic drug exposure itself could lead to changes in the brain that would increase the risk for a mental illness, particularly in persons with genetic vulnerability. For example, the high prevalence of smoking after individuals become depressed could reflect the antidepressant effects of nicotine and of monoamine oxidase A and B inhibition by cigarette smoke (Fowler et al. 2003). On the other hand, the reported risk for depression with early drug abuse (Brook et al. 2002) could reflect neuroadaptations in monoamine systems that might make individuals more vulnerable to depression.

The following table provides lifetime comorbidity (odds ratio) of alcohol and substance use dependence with three classes of psychiatric disorders among persons aged 18 and over in the United States.

Developmental Factors: Adolescence as a Critical Exposure Period

Normal developmental processes may result in higher risk for drug use at certain stages of the life cycle than others. Epidemiological data on patterns of drug use as well as animal studies support the notion of critical development periods for drug behavior (Purves et al. 2001). Experimentation most often starts in adolescence, as does the process of addiction (Wagner and Anthony 2002), a period during which the brain is still undergoing significant developmental changes (Dahl and Spear 2004). The percentage of children exposed to a drug of abuse during adolescence is not negligible. Monitoring the Future, a national study of drug use among high school students, reported that in 2006, the lifetime rates of use among adolescents in the 8th, 10th, and 12th grades for alcohol were 41%, 62%, and 73%, respectively; for cigarettes, 25%, 36%, and 47%, respectively; and for illicit substances, 21%, 36%, and 48%, respectively (University of Michigan 2006). Although the effects of drugs of abuse during this stage of development have not been adequately investigated, initial exposure during adolescence is associated with more chronic use, more intensive use, and greater risk of dependence compared with initiation at older ages (Figure 22–5). For example, epidemiological studies have provided evidence of an increased likelihood for the development of a substance use disorder when cigarette smoking, drinking, or the use of illicit drugs start early during adolescence (Anthony and Petronis 1995, Hingson et al. 2006, Kandel 2003, Kandel and Chen 2000, Volkow 2006). Normal adolescent-specific behaviors (such as risk-taking, novelty-seeking, response to peer pressure) increase the propensity of experimenting with legal and illegal drugs (Spear 2000), which might reflect incomplete development of brain regions (e.g., myelination of frontal lobe regions) involved in the processes of executive control and motivation (Sowell et al. 2003). The importance of adolescence as a critical developmental risk period for drug involvement and substance dependence is supported by work on rodents, which documents the greater vulnerability of adolescents than of adults to a variety of drugs. For example, in rats, exposure to nicotine during the period corresponding to adolescence is associated with greater nicotine self-administration than first exposure in adulthood, a difference that persists when the adolescent rats reach adulthood (Levin et al. 2003). Adolescent rats appear to be more sensitive than adult rats to the rewarding actions of nicotine (Belluzzi et al. 2004) and to nicotine-induced alterations in nicotine receptors (Adriani et al. 2003) in cholinergic systems in the cerebral cortex, midbrain, and hippocampus (Abreu-Villaca et al. 2003). In addition, enhanced expression of plasticity-related genes following injection of nicotine in adolescents compared with adult rats has been observed throughout the brain, but especially the forebrain (Schochet et al. 2005). Similar vulnerabilities in adolescence have been reported for alcohol (Rezvani and Levin 2004, Slawecki and Roth 2004, Ristuccia and Spear 2005), amphetamines (McPherson and Lawrence 2006), and morphine (White and Holtzman 2005). Future research should clarify whether neurobiological changes cause greater vulnerability of adolescents than of adults to addiction to nicotine (Kandel and Chen 2000) and alcohol (Grant et al. 2001).

Genetic Factors

It is estimated that 40–60% of the vulnerability to addiction is attributable to genetic factors (Uhl and Grow 2004). These factors play a less important role for initiation of substance abuse than dependence (Fowler et al. 2007, Lerman and Berrettini 2003). Multiple genes have been identified in animals as key to drug responses, and their modifications markedly affect drug self-administration (Laakso et al. 2002) (see below). In humans, several chromosomal regions have been linked to drug abuse, but only a few specific genes have been identified with polymorphisms (alleles) that either predispose to or protect from drug addiction (Uhl and Grow 2004). Some of these are polymorphisms that interfere with drug metabolism. For example, specific alleles for the genes that encode alcohol dehydrogenase ADH1B and acetaldehyde dehydrogenase ALDH2 (enzymes involved in the metabolism of alcohol) are reportedly protective against alcoholism (Chen et al. 1999). Similarly, polymorphisms in the genes for cytochrome P-450 2A6 and 2D6 (enzymes involved in nicotine and opioid metabolism, respectively) are reportedly protective against nicotine addiction (Rao et al. 2000) and codeine abuse (Kathiramalainathan et al. 2000).

Figure 22–5 Prevalence of lifetime drug dependence by age at first drug use in the US population aged 18 and over in 1992. The prevalence of lifetime dependence decreased steeply with increasing age of onset of drug use. Overall, the prevalence of lifetime dependence among those who started using drugs under the age of 14 years was about 34%, dropping sharply to 15.1% for those initiating use at age 17, to about 14% among those initiating use at the age of 21 or older. (Taken with permission from Grant and Dawson 1998.)
Some polymorphisms of genes that encode receptors that mediate drug effects have also been associated with a higher risk for addiction. For example, there is an association between alcoholism and the genes for the γ-aminobutyric acid-A (GABA_A) receptors, GABRG3 (Dick et al. 2004), GABRA2 (Edenberg et al. 2004), and nicotine dependence and the β3 nicotinic cholinergic receptor (Bierut et al. 2007). Dopamine D2 receptor polymorphisms have been linked to a higher vulnerability to drug addiction, although some studies have failed to replicate this finding (Uhl 2004). Replication for many of the genetic findings in substance abuse and addiction is still pending.

Environmental Factors (Adolescent Use and Vulnerability)

Environmental factors that have been consistently associated with the propensity to self-administer drugs include structural factors (such as low socioeconomic class), proximal factors (such as parental drug use and dependence, poor quality of parenting, parental depression, and peer influence), and more distal factors (such as drug availability, school, neighborhood characteristics, advertising, and the media) (Glantz and Hartel 1999, Hawkins et al. 1992, Petronis and Anthony 2000). Stress might be a common feature in a wide variety of environmental factors that increase the risk for drug abuse. The mechanisms responsible for stress-induced increases in vulnerability to drug use and to relapse in those addicted are not yet well-understood, but there is evidence that the stress-responsive neuropeptide corticotropin-releasing factor (CRF) is involved through its effects in the amygdala and the pituitary–adrenal axis (Koob 1999) (see below).

Imaging techniques now allow us to investigate how environmental factors affect the brain and how these, in turn, affect the behavioral responses to drugs of abuse. For example, in nonhuman primates, housing conditions and social status affects dopamine D1 receptor expression in the brain, which in turn affects the propensity for cocaine self-administration (Morgan et al. 2002). Animals that achieve a dominant status in the group show increased levels of dopamine D1 receptors and are reluctant to administer cocaine, whereas animals that are subordinate have lower dopamine D1 receptor levels and readily administer cocaine. Animal studies have shown that increasing dopamine D2 receptors in nucleus accumbens markedly decreases drug consumption (which has been demonstrated for alcohol) (Thanos et al. 2001), which could provide a mechanism by which a social stressor could modify the propensity to self-administer drugs.

Gene–Environment Interaction

Ultimately, understanding the etiology of substance use and dependence will require the examination of interactions among genetic and environmental factors (Compton et al. 2005b). Advances in human genetics make it easier as well to identify environmental factors. We now can test in experimental animals as well as in people how a genetic risk will be modified by environmental factors and vice versa. Ottman (1996) first outlined five potential patterns of gene–environment interactions. The genotype produces or increases the expression of the environmental risk factor; the genotype exacerbates the effect of the risk factor; exposure to the risk factor exacerbates the effect of the genotype, without which there would be no effect; both the genotype and the risk factor are required to increase the risk; the genotype and the risk factor each affect risk, and their joint effects can be higher or lower than the effect of each alone (Hernandez and Blazer 2006: Figure 8.1, p. 166). One of the first demonstrations of a gene–environment interaction was the finding by Caspi et al. (2003) that the neurotransmitter-metabolizing enzyme monoamine oxidase A moderated the effect of childhood maltreatment on the development of conduct disorder, antisocial personality, and adult violent crime among boys. People with low monoamine oxidase A levels were more likely to develop such problems than those with high levels.

Very few empirical studies have yet identified gene–environment interactions with respect to substance dependence. Caspi et al. (2005) found that a functional polymorphism in the catechol-O-methyltransferase gene increased the risk that an adolescent who used cannabis would meet criteria for schizophreniform disorder at age 26. Another recent illustration is the finding that team sport participation buffered the effect of two genotypes that confer risk for smoking (the dopamine reuptake transporter SLC6A3 and the dopamine receptor DRD2) on the progression of adolescent smoking (Audrain-McGovern et al. 2006).

Neuropharmacology of Drug Intoxication and Reward

Animal Models

Much of the recent progress in understanding the neurobiology of addiction has been derived from the study of animal models. While no animal model of addiction fully emulates human addiction, animal models do permit investigation of specific elements of the process of drug addiction. Such elements can be defined by models of different stages of the addiction cycle, models of psychological constructs such as positive and negative reinforcement, and models of actual symptoms of addiction.

Animal models of reward are extensive and well-validated. Animals and humans will readily self-administer drugs in the nondependent state. Drugs of abuse have powerful reinforcing properties such that animals will perform many different tasks and procedures to obtain the drugs, even in the nondependent state. Drugs that are self-administered by animals correspond well with those that have high abuse potential in humans, and intravenous self-administration by animals is considered predictive of abuse potential (Collins et al. 1984). Intravenous self-administration of drugs such as cocaine, methamphetamine, heroin, and nicotine in rodents and primates produces a characteristic pattern of behavior that lends itself to neuropharmacological study (Figure 22–6). Using this procedure, the dose, cost of responding, and second-order schedules (working for a stimulus [cue] that then allows the reinforcer to be delivered), all can be manipulated to determine the value of the reward. Similar studies have been performed and validated with oral self-administration of alcohol as a reward where animals will work to obtain meaningful blood alcohol levels (Samson 1986).

Two other animal models have been used extensively to indirectly measure drug reward: conditioned place preference and brain reward thresholds. Conditioned place preference assesses the reinforcing efficacy of drugs using a
classical or Pavlovian conditioning procedure. Here, animals experience two distinct neutral environments that are paired spatially and temporally with distinct drug or nondrug states, respectively. The animal is then given an opportunity to choose to enter and explore either environment, and the time spent in the drug-paired environment is considered an index of the drug’s reward value. Animals typically exhibit a conditioned place preference for an environment associated with drugs that are self-administered by humans and avoid environments that induce aversive states (for conditioned place aversion, see below).

Lowering the threshold of brain stimulation reward also reliably measures drug reward. Animals will self-administer electrical stimulation to certain brain areas, notably the origins and projections of the medial forebrain bundle, and humans have described stimulation of these areas as pleasurable. The hypothesis derived from Olds and Milner and the subsequent body of work show that brain stimulation reward directly stimulates neuronal circuits that are activated by natural reinforcers thus tapping directly into the brain reward circuitry. Drugs of abuse decrease thresholds for brain reward, and there is good correspondence between the ability of drugs to decrease brain reward thresholds and their abuse potential (Kornetsky and Bain 1990).

Types of Drugs
A key element of drug addiction is how the brain reward system changes with the development of addiction. Indeed, to understand how these systems change with the development of addiction, one must understand the neurobiological bases for acute drug reward. A principal focus of research on the neurobiology of the positive reinforcing effects of drugs of abuse has been to examine the origins and terminal areas of the mesocorticolimbic dopamine system, important in psychostimulant reward. This specific circuit has been broadened to include the many neural inputs and outputs that interact with the ventral tegmental area and the basal forebrain, and as such has been termed by some as the mesolimbic reward system (Figure 22–7).

Recently, specific components of the basal forebrain that have been identified with studies of drug reward have also focused on the “extended amygdala,” which includes the central nucleus of the amygdala, the bed nucleus of the stria terminalis, and a transition zone in the medial (shell) part of the nucleus accumbens. As the neural circuits for the reinforcing effects of drugs of abuse has become better understood, so has the role of the neurotransmitters/neuromodulators involved. Four systems have been identified as having an important role in the acute reinforcing effects of drugs of abuse: the mesolimbic dopamine system, the opioid peptide system, the GABA system, and the endocannabinoid system (Table 22–6). While some have argued for a drug reward system in series with the mesolimbic dopamine system, others have argued that as one moves away from the psycho-stimulant drugs, such as cocaine and amphetamines, the importance of dopamine diminishes, and other neurochemical systems may have drug reward functions independent of dopamine in the extended amygdala.
Neurochemical neurocircuits in drug reward

Stimulants

Early work on psychostimulants showed that destruction of the mesocorticolimbic dopamine system with a dopamine-specific neurotoxin blocked both the locomotor activation and rewarding effects of cocaine and methamphetamine (Roberts et al. 1980). Subsequent pharmacological studies revealed a key role for three of the five dopamine receptor subtypes (D₁, D₂, and D₃) and a localization of such effects to the medial parts of the nucleus accumbens (shell) and some activity in the central nucleus of the amygdala and bed nucleus of the stria terminalis (for review see Koob et al. 1998). Other neurochemical systems modulating the psychostimulant reward include serotonin and glucocorticoids.

Nicotine

As with psychostimulants, blockade and destruction of the mesocorticolimbic dopamine system with dopamine-specific neurotoxins blocks the acute rewarding effects of nicotine, but the neuropharmacological action has been hypothesized to be via nicotinic receptor activation of dopamine release primarily in the ventral tegmental area but also presynaptically in the nucleus accumbens (Watkins et al. 2000). However, nicotine reward as measured by conditioned place preference appears to be independent of the mesocorticolimbic dopamine system (Laviolette et al. 2002). Other substrates implicated in nicotine reward include cholinergic inputs to the pedunculopontine nucleus (Yeomans and Baptista 1997). In the ventral tegmental area, different nicotine receptor
subtypes and other neurotransmitter modulation suggest that nicotine acts via desensitization of α4, β2 nicotinic receptors and activation of GABAergic interneurons with simultaneous activation of α7 nicotinic receptors (Kelley 2002). Finally, activation of opioid peptide systems via the μ opioid receptor may contribute to the acute rewarding effects of nicotine (Berrendero et al. 2002).

**Alcohol**
Alcohol does not bind to a specific receptor but appears to activate ethanol receptive elements in hydrophilic pockets of proteins. Multiple neurotransmitter systems have been implicated in its rewarding effects, including GABA, opioid peptides, dopamine, serotonin, and glutamate. Systemic and local intracerebral administration of GABA_A antagonists and opioid antagonists block the acute rewarding effects of alcohol; and the most sensitive site appears to be the central nucleus of the amygdala. In addition, dopamine antagonists, cannabinoid CB_1 antagonists, and serotonin antagonists (serotonin-3 receptor and serotonin reuptake blockers) all have been shown to block ethanol reward as measured by oral self-administration of pharmacological amounts of ethanol in nondependent animals (Koob 2003). Ethanol at low doses may act as a glutamate antagonist specifically at the N-methyl-D-aspartate (NMDA) receptor, and this antagonism may also contribute to the acute rewarding effects of ethanol (Hoffman et al. 1989).

**Cannabis**
Neuropharmacological studies on cannabinoids have implicated both cannabinoid and opioid mechanisms. Opioid and cannabinoid CB_1 antagonists block intravenous self-administration of tetrahydrocannabinol (THC) in squirrel monkeys (Justinova et al. 2003). A role for the mesocorticolimbic dopamine system has been hypothesized based on indirect evidence that THC administration activates the release of dopamine in the shell of the nucleus accumbens similar to other drugs of abuse (Tanda et al. 1997).

**Opioids**
The analgesic actions of opioids are due to direct inhibition of nociceptive activity throughout the neuraxis including ascending pathways from the dorsal horn of the spinal cord and pain control circuits that descend from the midbrain back to the dorsal horn (Mansour et al. 1995). Neuropharmacological studies of opioid reward in nondependent animals have revealed key roles for activation of opioid receptors in the ventral tegmental area, pedunculopontine nucleus, nucleus accumbens, and central nucleus of the amygdala, both dependent and independent of the mesocorticolimbic dopamine systems (Koob et al. 1998). The key opioid receptor subtype involved in the rewarding effects of opioids is the μ opioid receptor. Activation of the κ opioid receptor, while producing analgesia, actually produces aversive dysphoric reactions. One region of overlap of the neural substrates for the rewarding effects of opioids and the effects of opioids on pain modulation is the central nucleus of the amygdala.

**Hallucinogens and Inhalants**
Data on hallucinogens and inhalants are limited to indirect measures of intoxication. Serotonin-2A antagonists block the drug discrimination stimulus effects of lysergic acid diethylamide (LSD) in animal studies (Gresch et al. 2007) and the psychedelic experience in humans (Glenon et al. 1984). Inhalants such as nitrous oxide produce analgesia that is blocked by opioid antagonists (Chen and Quock 1990), and self-administration of nitrous oxide is blocked by opioid antagonists (Wood et al. 1977). There is evidence of place preference to toluene in rats (Lee et al. 2004), which was blocked by administration of the GABA transaminase inhibitor γ-vinyl-GABA; however, little pharmacology is available on the mechanisms of action of toluene and other inhalants.

**Substance Dependence (Addiction)**

**Animal Models**
A large focus in animal studies has been on the synaptic sites and molecular mechanisms in the central nervous system on which drugs of abuse act initially to produce their rewarding effects (see above). Recently, however, a number of new animal studies have examined components

of the negative reinforcing effects of dependence and are beginning to explore how the nervous system adapts to drug use. In addition, there are models of craving involving drug-, cue- and stress-induced reinstatement of drug-seeking behavior. Finally, animal models have been designed to address the transition to addiction ranging from compulsive drug-taking, as measured by escalation in drug intake (Ahmed and Koob 1998), or drug-seeking despite negative or aversive consequences (Vanderschuren and Everitt 2004, Deroche-Gammonet et al. 2004). These models also have begun to address specific elements of the diagnostic criteria used by the American Psychiatric Association and the World Health Organization to define addiction or substance dependence (American Psychiatric Association 1994, World Health Organization 1992).

Rodents will increase self-administration of drugs during withdrawal from the dependent state (termed escalation) as measured both by increased self-administration of the drug and working harder to obtain the drug. Such increased self-administration in dependent animals has now been observed with cocaine, methamphetamine, nicotine, heroin, and alcohol (Ahmed and Koob 1998, Kitamura et al. 2006, O’Dell and Koob 2007, Ahmed et al. 2000, Roberts et al. 2000). Equally compelling are studies showing drug-taking in the presence of aversive consequences in animals with extended access to the drug. Rats with extended access to cocaine did not suppress drug-seeking in the presence of an aversive conditioned stimulus, which has face validity for the DSM-IV-TR criteria of “continued substance use despite knowledge of having a persistent physical or psychological problem” (Vanderschuren and Everitt 2004).

Animal models of craving (preoccupation/anticipation stage) involve both the conditioned rewarding effects of drugs of abuse and measures of the conditioned aversive effects of dependence (Shippenberg and Koob 2002). Resistance to extinction has been used to measure the residual motivational properties of drugs by assessing the persistence of drug-seeking behavior in the absence of response-contingent drug availability. Other measures of craving examine the motivational properties of the drugs themselves, or cues paired with the drugs, after extinction. Drug-induced reinstatement first involves extinction, and then presentation of a priming injection of a drug. Latency to reinitiate responding, or the amount of responding on the previously extinguished lever are hypothesized to reflect the motivation for drug-seeking behavior. Similarly, drug-paired or drug-associated stimuli can reinitiate drug-seeking behavior (cue-induced reinstatement). Other measures of craving include second-order schedules where animals can be trained to work for a previously neutral stimulus that predicts drug availability.

From the aversive side, acute stressors can also reinitiate drug-seeking behavior in animals that have been extinguished, and this is called stress-induced reinstatement. Increased brain reward thresholds and increased anxiety-like behavior have been shown to persist after acute withdrawal in animals studies and have been hypothesized to reflect protracted abstinence. Finally, with opioids, conditioned withdrawal has been observed. Previously neutral stimuli paired with precipitated opioid withdrawal have been shown to produce place aversions and motivate increasing self-administration of opioids (Kenny et al. 2006).

### Brain Circuitry Neuroadaptations

#### Reward Circuit

The reinforcing effects of drugs during intoxication set the initial stage that, if perpetuated, triggers the neuronal adaptations that result in addiction. Imaging studies in drug abusers as well as nondrug abusers have shown that drugs of abuse increase the extracellular concentration of dopamine in the striatum (where the nucleus accumbens is located) and that these increases are associated with their reinforcing effects. Subjects having the greatest increases in dopamine were the ones that perceived drug effects such as “high,” “rush,” or “euphoria” most intensely (Laruelle et al. 1995, Volkow et al. 1999b, Drevets et al. 2001). These studies also showed that the reinforcing effects appeared to be associated not only with the magnitude of the dopamine increase but also with the abruptness of the increase. Thus, for an equivalent increase in dopamine, the drug was perceived as reinforcing when it was injected intravenously, which leads to fast drug uptake in the brain and presumably very fast changes in dopamine concentration, but not when it was given orally (Volkow et al. 2001), which leads to a slow rate of brain uptake and presumably slow increases in dopamine concentration. The relation of the reinforcing effects of drugs to fast and large increases in dopamine concentration parallels the fast changes in dopamine concentration induced by phasic dopamine cell firing (fast burst firing >30 Hz) (Wightman and Robinson 2002), which mediates the salience of stimuli (Grace 2000). This contrasts with tonic dopamine cell firing (slow firing at frequencies of around 5 Hz) (Wightman and Robinson 2002), which maintains baseline steady-state dopamine levels, whose function is to set the overall responsiveness of the dopamine system. These findings have led to the hypothesis that by inducing changes in dopamine concentration that mimic, but exceed those produced by phasic dopamine cell firing, drugs of abuse overactivate the neuronal processes of saliency, accounting for their high reinforcing value.

However, increases in dopamine concentration during intoxication occur in both addicted and nonaddicted subjects, so this by itself cannot explain the process of addiction. Since drug addiction requires chronic drug administration, it seems likely that addiction results from the repeated perturbation of reward circuits (marked dopamine increases followed by dopamine decreases) and the consequent disruption of the circuits that it regulates (motivation/drive, memory/learning, and control). Indeed, imaging studies in drug-addicted subjects have consistently shown long-lasting decreases in the numbers of dopamine D2 receptors in drug abusers when compared with controls (Volkow et al. 2002) (Figure 22–8). In addition, cocaine abusers also have decreased activity, as demonstrated by reduced dopamine release in response to a pharmacological challenge with a stimulant drug (Volkow et al. 1997). The decrease in the number of dopamine D2 receptors, coupled with the decrease in dopaminergic activity, in the abusers could well result in a decreased sensitivity of reward circuits to stimulation by natural reinforcers. This decreased sensitivity would lead to decreased interest in ordinary environmental stimuli, possibly predisposing subjects to seek drug stimulation as a means to activate these reward circuits. Imaging studies provide evidence of disrupted sensitivity to natural reinforcers...
in addiction. For example, in a study by Martin-Solch et al. (2001), the mesostriatal and mesocorticolimbic circuits of opiate addicts were not activated in response to natural reinforcers whereas they were in control subjects. Similarly, in a second study by the same group, dopamine-regulated reward centers in tobacco smokers failed to activate in response to monetary reward. Interestingly, decreased sensitivity of reward circuits to acute alcohol administration has also been documented in cocaine abusers when compared to control subjects (Volkow et al. 2000). These findings suggest an overall reduction in the sensitivity of reward circuits in drug-addicted individuals not only to natural reinforcers but also possibly to drugs that are different from the drug to which they are addicted.

Drive/Motivation Circuit

During addiction, the value of the drug as a reinforcer is hypothesized to be so much greater than that of any other natural reinforcer that natural reinforcers can no longer compete as viable alternatives, and the enhanced “saliency value” of the drug becomes fixed. This is in contrast to natural reinforcers for which the saliency is momentary and decreases with exposure to the reinforcer (D’Chiara 2002) or by the presentation of alternative, more appealing reinforcers. One of the areas of the brain involved in shifting the relative value of reinforcers is the orbitofrontal cortex (Schultz et al. 2000, Rolls 2000).

Imaging studies have provided evidence of disruption of the orbitofrontal cortex during addiction (reviewed in Volkow and Fowler 2000). The orbitofrontal cortex appears to be hypoactive in drug-addicted subjects tested during withdrawal (Volkow et al. 1992, Adinoff et al. 2001), which may reflect the lack of stimulation by salient stimuli during detoxification. In contrast, in active cocaine abusers, the orbitofrontal cortex has been shown to be hypermetabolic in proportion to the intensity of the craving experienced by the subjects (Volkow et al. 1991). Since increased orbitofrontal cortex activation has been associated with compulsive disorders (Insel 1992), activation of the orbitofrontal cortex in addicted subjects may contribute to the compulsive drug intake. Indeed, preclinical studies have shown that damage of the orbitofrontal cortex results in a behavioral compulsion to procure the reward even when it is no longer reinforcing (Volkow and Fowler 2000). This is consistent with the descriptions by drug addicts who claim that once they start taking the drug, they cannot stop even when the drug is no longer pleasurable. Exposure to the drug or drug-related stimuli in the withdrawal state reactivates the orbitofrontal cortex and may be responsible for the compulsive drug intake that ensues. Indeed, activation of the orbitofrontal cortex has been reported during drug intoxication in drug-addicted, but not in nondrug-addicted, subjects and the level of activation predicted the intensity of drug-induced craving (Volkow et al. 1999a, Brody et al. 2002). Similarly, activation of the orbitofrontal cortex has been reported during exposure to drug-related cues when these elicit craving. Since the orbitofrontal cortex also processes information associated with the prediction of reward (Schultz et al. 2000), its activation during cue-exposure could signal reward prediction, which could be perceived as craving by the addicted subject.

In detoxified drug abusers, the decreased activity in the orbitofrontal cortex is associated with reductions in the numbers of dopamine D2 receptors in striatum (Volkow et al. 1992).
1993, 2001). Since dopamine D2 receptors transmit reward signals into the orbitofrontal cortex, this association could be interpreted as a disruption of the orbitofrontal cortex, secondary to changes in striatal dopamine activity (such as lack of stimulation during withdrawal and enhanced stimulation with exposure to drugs or drug-related cues). However, since striatal-frontal connections are bidirectional, this association could also reflect the disruption of the orbitofrontal cortex, which then deregulates dopamine cell activity.

**Emotional Circuit**

Addiction also involves a long-term, persistent plasticity in the activity of neural circuits mediating motivational systems that derives from recruitment of antireward systems that drive aversive states. Antireward is a concept developed based on the hypothesis that there are brain systems in place to limit reward (Koob and Le Moal 1997), an opponent process concept that forms a general feature of biological systems. The concept of an antireward system is derived from the hypothesis of not only a within-system neuroadaptation, such as a loss of dopamine function (see above), but also a between-system neuroadaptation to activation of the reward system at the neurocircuitry level. Here, a between-system neuroadaptation is a circuitry change where circuit B (antireward circuit) is activated by circuit A (reward circuit).

The withdrawal-negative affect stage defined above consists of key motivational elements such as chronic irritability, emotional pain, malaise, dysphoria, alexithymia, and loss of motivation for natural rewards, and is characterized in animals by increases in reward thresholds during withdrawal from all major drugs of abuse. Significant plasticity occurs in the neurotransmitter circuits identified as critical for the acute reinforcing effects of drugs of abuse. In animal models of the transition to addiction, increases in brain reward threshold (decreased reward) occur that temporally precede and highly correlate with escalation in drug intake (Ahmed et al. 2002). During acute withdrawal, there is decreased activity of the reward systems as well as decreased opioid peptide, GABA, glutamate, and neuropeptide Y activity in elements of the extended amygdala and/or nucleus accumbens (see above).

However, as dependence and withdrawal develop, brain antireward systems such as corticotropin-releasing factor (CRF), norepinephrine, and dynorphin are recruited (Figure 22–9). For example, extracellular CRF in the extended amygdala is increased during acute withdrawal from drugs of abuse, and critically, CRF antagonists block excessive drug-taking during dependence (Koob 2003). These neurotransmitter systems are known to be activated during the development of excessive drug-taking as a between-system opponent process (see above), and this activation is manifest when the drug is removed (acute withdrawal and protracted abstinence). The observation that CRF receptor antagonists in the amygdala can block excessive drug intake associated with the development of dependence provides a compelling example of a key aspect of the plasticity of the extended amygdala in the development of addiction. Thus, antireward circuits are recruited as between-system neuroadaptations (Koob and Bloom 1988) during the development of addiction, producing aversive or stress-like states (Koob 2003, Nestler 2001, Aston-Jones et al. 1999). Within the motivational circuits of the extended amygdala, the combination of decreases in reward neurotransmitter function and recruitment of antireward systems provides a powerful source of negative reinforcement contributing to compulsive drug-seeking behavior and addiction. The development of the aversive emotional state that drives the negative reinforcement of addiction may also contribute to the critical problem in drug addiction of chronic relapse, where addicts return to compulsive drug-taking long after acute withdrawal (Koob and Le Moal 2005). Neurotransmitter/neuromodulator systems implicated in stress-induced relapse include CRF, glucocorticoids, and norepinephrine, suggesting reactivation of antireward systems during relapse (Piazza and Le Moal 1996, Shaham et al. 2000, See et al. 2003). Thus, the dysregulation of emotional processing may persist during protracted abstinence to set the tone for vulnerability to “craving” by activation of the drug-, cue-, and stress-induced reinstatement circuits, now augmented by a hypo-functioning prefrontal system (Le Moal 1995).
Control/Executive Function Circuit
One of the most consistent findings from imaging studies is that of abnormalities in the prefrontal cortex including the anterior cingulate gyrus in drug-addicted subjects (reviewed in Goldstein and Volkow 2002). The prefrontal cortex is involved in decision-making and in inhibitory control (Royall et al. 2002). Thus, its disruption could lead to inadequate decisions that favor immediate rewards over delayed but more favorable responses. It could also account for the impaired control over the intake of the drug even when the addicted subject expresses the desire to refrain from taking the drug (Goldstein and Volkow 2002). Thus, one could expect that the disruptions of self-monitoring and decision-making processes that are observed in drug-addicted subjects (Bechara and Damasio 2002, Ernst et al. 2003) are in part related to disrupted prefrontal functions. Moreover, preclinical studies show that chronic administration of cocaine or amphetamine result in a significant increase in dendritic branching and in the density of dendritic spines in the prefrontal cortex (Robinson et al. 2001). These changes in synaptic connectivity could be involved in the changes in decision-making, judgment, and cognitive control that occur during addiction. Indeed, imaging studies have shown evidence of changes in prefrontal activation during a working memory task in smokers compared to ex-smokers (Ernst et al. 2001).

Disruption of the prefrontal cortex could lead to loss of self-directed/willed behavior in favor of automatic sensory-driven behavior. Moreover, the disruption of self-controlled behavior is likely to be exacerbated during drug intoxication from prefrontal disinhibition of the amygdala (Rosenkranz and Grace 2001). The disinhibition of prefrontal top-down control would release behaviors that are normally kept under close monitoring, and simulate stress-like reactions in which inhibitory control is suspended and stimulus-driven behavior is accentuated (Goldstein and Volkow 2002).

Learning/Memory Circuit
The relevance of learning and memory in addiction is made evident by the pernicious effect that a place, a person, or a cue (that brings back memories of the drug) has on the addict who is trying to remain drug-free. These factors trigger an intense desire for the drug (craving) and, not infrequently, relapse. Multiple memory systems have been proposed in drug addiction including conditioned incentive learning (mediated in part by nucleus accumbens and amygdala), habit learning (mediated in part by the caudate and putamen), and declarative memory (mediated in part by the hippocampus) (White 1996). Through conditioned incentive learning, the neutral stimuli, coupled with the drug of abuse, acquire reinforcing properties and motivational salience even in the absence of the drug. Through habit learning, well-learned sequences of behavior are elicited automatically by the appropriate stimuli. Finally, declarative memory has been related to the learning of affective states in relationship to drug intake.

Memory circuits are likely to influence the effects of the drug during intoxication since they set the expectations of the drug effects in the addicted subject (Kirk et al. 1998). Activation of regions linked with memory has been reported during drug intoxication (Breiter et al. 1997, Stein et al. 1998) and during craving induced by drug exposure, video, or recall (Grant et al. 1996, Childress et al. 1999, Knilts et al. 2001, Wang et al. 1999). Also, studies in drug abusers suffering withdrawal have shown evidence of decreased D2 receptor expression and decreased dopamine release in the dorsal striatum (Volkow et al. 1997). In animal studies, the drug-induced changes in the dorsal striatum are observed after longer drug exposures than those observed in the nucleus accumbens, and have been interpreted to reflect further progression into the addicted state (Letchworth et al. 2001). This is relevant since involvement of the dorsal striatum, which is a region associated with habit learning, indicates that in drug addiction the routine associated with drug consumption may be triggered automatically by exposure to the drug or drug-related cues (Io et al. 2002).

Molecular Neuroadaptations
The common neurocircuitry actions of drugs of abuse and the change in plasticity of these circuits (see above), have long been hypothesized to involve molecular neuroadaptations that either drive the weighting of the circuits or result from the changes in activity of the circuits or both (Figure 22–10). Repeated perturbation of intracellular signal transduction pathways may cause changes in neuronal function or nuclear function and altered rates of transcription of particular target genes. Altered expression of such genes would lead to presumably long-term altered activity of the neurons where such changes occur, and ultimately to changes in neural circuits in which those neurons operate.

Transduction Factors
Signal transduction mechanisms are one of the key molecular changes following acute administration of drugs of abuse. Dopamine acutely activates and inhibits G-proteins via Gs (D1 family) and Gi (D2 family). Opioids produce their effects in target neurons via interactions with μ, δ, and κ classes of receptors, which are coupled via pertussis toxin-sensitive G-protein binding proteins and acutely inhibit adenylyl cyclase (Law et al. 2000).

Activation of opioid receptors also leads to recruitment of Gs, and related G proteins, which leads to the inhibition of adenylyl cyclase and of the cyclic adenosine monophosphate (cAMP) protein phosphorylation cascade (Gutstein and Akil 2001). Recruitment of Gs also leads to activation of certain K+ channels and inhibition of voltage-gated Ca2+ channels, although the two actions occur to varying extents in different neuronal cell types. Both are inhibitory actions—more K+ flows out of the cell and less Ca2+ flows into the cell—that mediate some of the relatively rapid inhibitory effects of opioids on the electrical properties of their target neurons. Similarly, reductions in cellular Ca2+ levels alter Ca2+-dependent protein phosphorylation cascades. Altered activity of these protein phosphorylation cascades, which also can vary among different cell types, leads to the regulation of still additional ion channels which contribute further to the acute effects of the drug (Nestler 2004, Nestler and Malenka 2004).

However, chronic exposure to opioids increases adenylyl cyclase (Sharma et al. 1975, Collier and Francis 1975), leading to other perturbations in intracellular messenger pathways, including protein phosphorylation mechanisms. These perturbations eventually elicit changes in many other neural processes within target neurons (Nestler 2004, Nestler and
Figure 22–10 Molecular mechanisms of neuroadaptation. Cocaine and amphetamines, as indirect sympathomimetics, stimulate the release of dopamine which acts at G protein-coupled receptors, specifically D₁, D₂, D₃, D₄, and D₅. These receptors modulate the levels of second-messengers like cyclic adenosine monophosphate (cAMP) and Ca²⁺, which in turn regulate the activity of protein kinase transducers. Such protein kinases affect the functions of proteins located in the cytoplasm, plasma membrane, and nucleus. Among membrane proteins affected are ligand-gated and voltage-gated ion channels (VGCC). G and G proteins also can regulate potassium and calcium channels directly through their βγ subunits. Protein kinase transduction pathways also affect the activities of transcription factors. Some of these factors, like cAMP response element binding protein (CREB), are regulated posttranslationally by phosphorylation; others, like Fox, are regulated transcriptionally; still others, like Jun, are regulated both posttranslationally and/or transcriptionally. While membrane and cytoplasmic changes may be only local (e.g., dendritic domains or synaptic boutons), changes in the activity of transcription factors may result in long-term functional changes. These may include changes in gene expression of proteins involved in signal transduction and/or neurotransmission, resulting in altered neuronal responses. For example, chronic exposure to psychostimulants has been reported to increase the levels of protein kinase A (PKA) and adenyl cyclase in the nucleus accumbens and to decrease the levels of Gₐα. Chronic exposure to psychostimulants also alters the expression of transcription factors themselves. CREB expression, for instance, is depressed in the nucleus accumbens by chronic cocaine treatment. Chronic cocaine induces a transition from Fos induction to the induction of the much longer lasting Fos-related antigens (Fras) such as ΔFosB. Opioids, by acting on neurotransmitter systems, affect the phenotypic and functional properties of neurons through the general mechanisms outlined in the diagram. Examples of ligand-gated ion channels such as the γ-aminobutyric acid-A (GABAₐ) and glutamate N-methyl-D-aspartate (NMDA) receptor (NMR) and G protein-coupled receptors such as opioid, dopamine (DA), or the cannabinoid CB₁ receptors, among others, are shown. These receptors modulate the levels of second messengers like cAMP and Ca²⁺, which in turn regulate the activity of protein kinase transducers. Chronic exposure to opioids has been reported to increase levels of protein kinase A and adenyl cyclase in the nucleus accumbens and to decrease the levels of Gₐα. Chronic exposure to opioids also alters the expression of transcription factors themselves. CREB expression, for instance, is depressed in the nucleus accumbens and increased in the locus coeruleus by chronic morphine treatment, while chronic opioid exposure activates FRAs such as ΔFosB. Alcohol, by acting on neurotransmitter systems, affects the phenotypic and functional properties of neurons through the general mechanisms outlined in the diagram. Examples of ligand-gated ion channels such as the GABAₐ and the NMDA receptor and G protein-coupled receptors such as opioid, dopamine, or the cannabinoid CB₁ receptors, among others, are shown. The latter also is activated by endogenous cannabinoids such as anandamide. These receptors modulate the levels of second messengers such as cAMP and Ca²⁺, which in turn regulate the activity of protein kinase transducers. Such protein kinases affect the functions of proteins located in the cytoplasm, plasma membrane, and nucleus. Among membrane proteins affected are ligand-gated and VGCCs. Alcohol, for instance, has been proposed to affect the GABAₐ response via protein kinase C (PKC) phosphorylation. Gₐ and Gₜ proteins also can regulate potassium and calcium channels directly through their βγ subunits. Chronic exposure to alcohol has been reported to increase levels of protein kinase A and adenyl cyclase in the nucleus accumbens and to decrease the levels of Gₐα. Moreover, chronic ethanol induces differential changes in subunit composition in the GABAₐ and
transcription factors, isoforms of fos, FosB, Fra-1, and Fra-2 in the nucleus accumbens, other transcription factors, isoforms of ΔFosB, accumulate over longer periods of time (days) with repeated drug administration. Animals with activated ΔFosB have exaggerated sensitivity to the rewarding effects of drugs of abuse, and ΔFosB may be a sustained molecular “switch” that helps to initiate and maintain a state of addiction (Nestler 2005).

Molecular Genetic Evidence

Genetic and molecular genetic animal models have provided some convergent support for the neuropharmacological substrates identified in neurocircuitry studies. High-alcohol-prefering rats have been bred that show high voluntary consumption of alcohol, increased anxiety-like responses, and numerous neuropharmacological phenotypes such as decreased dopaminergic activity and decreased neuropeptide Y activity. In an alcohol-prefering and -nonpreferring cross, a quantitative trait locus was identified on chromosome 4, a region to which the gene for neuropeptide Y has been mapped. In the inbred preferring and nonpreferring quantitative trait loci analyses, loci on chromosomes 3, 4, and 8 have been identified which correspond to loci near the genes for the dopamine D3 and serotonin-1B receptors.

Gene knockout and transgenic knockin approaches have led to the ability to systematically inactivate the genes that control the expression of proteins that make up neurotransmitter and neuromodulator receptors and ligands in the central nervous system. Whereas these approaches do not guarantee that these genes are the ones that convey vulnerability in the human population, they provide viable candidates for exploring the genetic basis of endophenotypes associated with addiction.

Opioid-related gene knockout studies in mice have focused on knockout of the μ opioid receptor. Opiate (morphine) reinforcement as measured by conditioned place preference or self-administration is absent in μ knockout mice, and there is no development of somatic signs of dependence on morphine in these mice. Knockout of the μ opioid receptor also decreases nicotine reward, cannabinoid reward, and alcohol drinking in mice.

Knockout and neuropharmacological studies have implicated numerous neurotransmitter systems in ethanol preference, including opioid, dopamine, GABA, and serotonin. Novel modulatory effects on ethanol preference changes in the neurocircuits outlined above and are critical for breaks with reward homeostasis in addiction.
have been suggested by protein kinase and G-protein-activated inwardly rectifying K⁺ channel knockout studies (Crabbe et al. 2006).

Selective deletion of the genes for expression of different dopamine receptor subtypes and the dopamine transporter has revealed significant effects on challenges with psychomotor stimulants. Dopamine D₁ receptor knockout mice show blunted responses to the locomotor-activating effects of cocaine and amphetamine and in their acquisition of intravenous cocaine self-administration compared to wildtype mice. D₂ knockout mice have severe motor deficits and blunted responses to psychostimulants and opiates, but the effects on psychostimulant reward are less consistent. Dopamine transporter knockout mice are dramatically hyperactive but also show a blunted response to psychostimulants. Although compensatory developmental factors must be taken into account, it is clear that D₁ and D₂ receptors and the dopamine transporter play important roles in the actions of psychomotor stimulants.

Introduction

Autism as a specific syndrome was first described in the scientific literature in 1943 by Leo Kanner, a preeminent child psychiatrist at Johns Hopkins University (Kanner 1943). Drawing from his wealth of experience about early psychiatric and developmental disorders, he identified a set of common features of 11 children seen over a 5-year period that set them apart, and “…whose condition differed so markedly and uniquely from anything reported so far” (p. 217). His first paper described the presenting “fascinating peculiarities” of these 11 children, and his later papers followed their development over time.

Kanner described a range of individual differences in the language ability among the children, but also a set of core features, the most important of which was “the children’s inability to relate themselves in an ordinary way to people and situations from the beginning of life” (p. 242). The parental phrases that he quoted: “happiest when left alone, acting as if people weren’t there, oblivious to everything around him”—are phrases that parents in 2007 still use to describe their children during diagnostic evaluations.

Kanner (1971) followed nine of these 11 children into adulthood. There was some improvement in all symptoms during the school-aged period. Yet all of the individuals continued to lack normal social relations and only two adults were eventually employed, although still single and living with their parents.

Hans Asperger, a German pediatrician, wrote a paper in 1944 (Asperger 1944) that echoed many of Kanner’s descriptions, although it was not available to English readers for a number of years. Asperger also used the term “autistic” to refer to his patients and also emphasized that impairment in social integration was primary to the disorder and lifelong, affecting the child’s relations to the whole environment. Like Kanner, Asperger emphasized that this difference was present from early in life, and not a progressive event as seen in schizophrenia. He underscored the pervasive nature of the condition: “it totally colours affect, intellect, will, and action” (p. 39). However, Asperger described a degree of loquaciousness, intellectual ability in math and reading, and aggression and conduct problems. The latter do not figure prominently in Kanner’s patients, perhaps due to differences in age and functioning levels of the two groups of patients. Unlike Kanner, Asperger also described an abnormal relation to objects, involving abnormal fixations, collections, and lengthy monologues about these special interests.

Both Kanner and Asperger commented on the individual differences and range of levels and outcomes seen in their patients and attributed this to biological variation in the condition. Both were also of the view that there was a strong genetic contribution. Kanner, in particular, foresaw that the incidence of autism would increase as the field learned how to differentiate it from other developmental and childhood psychiatric conditions.

Epidemiology of Autism

The current rate of autism in the population has been a cause for marked concern and focused research from many different perspectives, including brain science, toxicology, education, and social policy. Prevalence estimates have increased in the past 15–20 years by more than 10-fold (Chakrabarti and Fombonne 2005) from a widely accepted figure of five cases per 10,000 to current estimates of one in 150 (Kuehn 2007) for autism spectrum disorders.

While some reasons for the change are understood, others are not, fueling both concern within the parent community and scientific interest in the biologies of autism. Some of the change is clearly artifactual, due to increased sensitivities in diagnosis (Fombonne 2005, Newschaffer et al. 2007) and the widening of diagnostic definitions. While definitions of autism 20 years ago reflected the more classic and severe presentation of the disorder, the current DSM-IV-TR classification system (American Psychiatric Association 2000) now includes both children who meet...
full criteria for autistic disorder (AD) and those who do not meet these stringent criteria are classified instead as Asperger disorder, or the even less specified diagnosis of pervasive developmental disorder—not otherwise specified (PDD-NOS). A number of epidemiological studies have examined the prevalence of children diagnosed with PDD-NOS and found it to be higher than those with AD (Baker 2002, Yeragin-Allsopp et al. 2003, Chakrabarti and Fombonne 2005). Thus, including both of these diagnostic groups would more than double prevalence rates. Therefore, the group of persons now being counted in prevalence studies includes many who would not have been counted based on earlier diagnostic definitions of autism.

Social practices have also affected autistic spectrum disorder (ASD) screening and diagnosis. Due to public policies involving educational practices for children with ASD, more special education services and other types of supportive and habilitative services have become available. Such interventions often have diagnostic criteria for inclusion and thus have led to greatly increased use of differential assessments that identify autism, particularly in school-aged and younger children, when the symptoms are clearest. Greater diagnostic attention has likely identified many more cases (Chakrabarti and Fombonne 2005, Gurney et al. 2003).

A variety of biological causes have also been suggested to account for some of the increasing prevalence rates of autism spectrum disorders. Environmental exposures, particularly mercury exposure through vaccinations, dental procedures, and environmental contaminants; increased use of fertility treatments; interactions between immune abnormalities in mother or child and exposure to immune challenges in the uterine or postuterine environments; and air and environmental pollutants such as heavy metals and PCBs (Newschaffer et al. 2007) have increased significantly in the past decade. Most important, understanding the changing prevalence rates is frustratingly limited at this time by our lack of knowledge of the underlying biology of autism.

**Diagnosis and Behavioral Features**

**Core Behavioral Features of Autism**

The first key features Kanner described were that his patients were oblivious to the social world, not unaware but uninterested. They ignored speech to such an extent that some were considered to be deaf, although none had a hearing impairment. The children ignored the comings and goings of their parents, the presence of strangers, and the presence of other children (Kanner 1943). Kanner described what is now considered to be the most severe form of a continuum of impairment in reciprocal social relatedness. Wing (1981) has suggested three main types of relatedness impairments in ASD: aloof (as Kanner described), passive (responsive to others’ interactions but not initiating interactions themselves), and active but odd (clearly interested in social interaction but very unusual in the way they go about it).

Children demonstrate social reciprocity in a variety of ways, including patterns of eye gaze, shared emotional expressions, social body postures, and gestures. This capacity is present in human development from the first few months of life, in gestures such as raising arms up to be lifted, use of eye contact to communicate, and use of facial expressions directed to others to communicate feelings (Stern 1985, Trevarthen and Aitken 2001). These are all affected in autism across age and spectrum of ability levels (Hobson and Lee 1999, Wimpory et al. 2000).

A second key feature of autism involves abnormal development and use of language. This may involve abnormal rhythm, rate, and prosody of speech. A significant number of persons with autism do not acquire speech. This group typically does not develop an alternative communication system of gestures or icons without extensive instruction. Thus, this subgroup lacks verbal and nonverbal communicative behaviors.

For those who develop speech in the preschool period, speech appears less a system for sharing thoughts, feelings, desires, and experiences with others and more a system of naming objects. Children with autism rely much more heavily on repetition, or echolalia, for language learning than others. Development of sentences is typically delayed and marked by echolalia (repetition of other’s sentences), with resulting pronoun confusion. More verbal children eventually master the syntactic rules, but for them language is very literal and they often have difficulty with metaphor, irony, and humor (Tager-Flusberg et al. 2005).

A lack of variation in daily behaviors is also characteristic of children with autism. They have a narrow range of activities and interests and devote large amounts of time to repetitive and ritualized behaviors. Motor stereotypes such as hand flapping, toe walking, finger movements, odd visual behaviors, repetitive words, or other vocalizations are also common. Rituals and routines may involve consistent patterns of grouping objects or insisting that household objects not be moved or changed. This feature was quite evident in Kanner’s first patients (Kanner 1943), and these behaviors continue to be an important part of the diagnostic picture (DSM-IV-TR, American Psychiatric Association 2000).

Many children and adults with autism have unusual reactions to the sensory world. Kanner (1943) described these symptoms in many of his early cases. Feeding, an early difficulty for six of them to the point of requiring tube feeding, resolved in all. Many children with autism respond strongly to loud noises and moving objects, although they themselves could make just as loud noises without being upset. Fascination with moving objects, water, watching the wheels of cars and trains spin, elevator doors, and feeling textures may go hand in hand with severe aversions to clothing textures, food textures, certain sounds, and negative reactions to haircuts or hair washing. Sensory over- or under-responsiveness may be seen in any sensory domain, and in the same child. The adult autobiographical literature gives vivid descriptions of the degree of difficulty this symptom can cause in everyday life (Grandin 1992, Williams 1992).

**Current Diagnostic Definitions**

In the United States, the diagnosis of ASD is made according to the DSM-IV-TR criteria. ASD, or pervasive developmental disorders (the DSM-IV-TR generic term for ASD), involves five diagnostic groups: AD, Asperger disorder, PDD-NOS, childhood disintegrative disorder, and Rett disorder.

The criteria for AD take precedence over all other diagnoses. The diagnostic criteria for AD involve demonstrating...
a total of six or more of the listed symptoms, including two from the social communication category, one from language category, and one from the restricted and repetitive behaviors category. The DSM-IV-TR dictates that if a child meets criteria for AD, that diagnosis must be assigned. Diagnoses involving Asperger disorder and PDD-NOS should only be used for cases that fail to reach criteria for AD.

The two other diagnoses, Rett syndrome and childhood disintegrative disorder, are generally not currently considered part of the pervasive developmental disorder group. Rett syndrome is a single gene mutation involving the MECP2 gene. It affects mostly girls, is progressive in its course, and results in very severe intellectual impairment and profound disability in all areas of functioning over time. While the surface features of Rett syndrome may resemble AD at its early stages, it differs in many symptoms, in onset patterns, in course, and in response to treatment.

Childhood disintegrative disorder is a very rare condition in which a fairly rapid regression occurs, generally between the third and fifth years, in children previously developing typically. The regression is marked by a dramatic loss of language abilities, onset of motor abnormalities, severe anxiety, and profound changes in social engagement and activities. After an initial regression, the functioning level stabilizes, and after that point children appear indistinguishable from other children with fairly severe AD and intellectual deficits (Volkmar and Klin 2005).

**Diagnostic Practices, Tools, and Problems**

The diagnosis of pervasive developmental disorder is made from three types of diagnostic procedures: a detailed history from parental interviews, parental description of current functioning in typical situations, and clinical observation and assessment of the child’s behavior. Recent developments in assessment tools have made the diagnosis of autism much more reliable. In fact, the diagnosis of AD among experienced clinicians has the highest rate of inter-rater agreement and the most stability of any of the psychiatric diagnoses. However, as with any behavioral disorder, diagnostic agreement is strongest in the moderate range of symptoms. There is less inter-rater agreement at the mildest end of the pervasive developmental disorder spectrum, and in the end where very severe intellectual deficits are also present (Lord 2005).

Unlike most other psychiatric and developmental diagnoses, autism is diagnosed from infancy through adulthood, and in persons, which range from intellectual impairment to normal and to gifted intellects. This large range of functioning within autism results in very few tools that can discriminate autism at all ages and all functioning levels. Clinicians need to choose diagnostic instruments accurately that will best differentiate autism from other diagnostic conditions (Lord 2005). The most common tools for ascertaining pervasive developmental disorder participants in research studies include the autism diagnostic inventory (ADI-R), an experimenter-administered interview, the social communication questionnaire, a parent questionnaire with key questions from the ADI-R, the autism diagnostic observational scale (ADOS), an interactive semistructured interview with the child or adult being diagnosed, and the childhood autism rating scales (CARSs), an examiner behavior rating system completed after a developmental evaluation.

**Medical and Other Comorbid Features**

As the prevalence of autism spectrum disorders has increased over the last two decades, parents, clinicians, and researchers have attended to a variety of common comorbid symptoms. Some of these were already described, at least in some form, by Kanner and Asperger.

**Seizures**

While epilepsy has long been associated with autism spectrum disorders, the proportion of patients reported to demonstrate comorbid seizure disorder varies from 5% to 44% (Tuchman and Rapin 2002). A recent study (Hara 2007) carried out a follow-up of 135 patients with idiopathic autism. Of these, 33 of the follow-up group (25%) exhibited epileptic seizures, which had an onset between 8 and 26 years of age. Two types of seizure were observed: partial seizures with secondarily generalized seizure (in 61%) and generalized seizure. While 18% of the nonepileptic group exhibited epileptic discharges on EEG, 68% of the epileptic group revealed epileptiform EEG findings before the onset of epilepsy. Some studies have found an association between low IQ and the occurrence of epilepsy (Pavone et al. 2004) or low IQ and motor deficit and epilepsy (Tuchman et al. 1991). As in the Hara (2007) study, abnormal or epileptiform EEG is also observed in substantial numbers of individuals with autism who do not have seizures (Tuchman et al. 1991, Tuchman and Rapin 1997). While the presence of seizure disorder and its association with other aspects of autism may provide interesting clues to the underlying pathophysiology, it remains unclear to what extent epileptiform activity is a core attribute of autism spectrum disorders.

**Anxiety**

In Kanner’s (1943) original description of autism, he noted unusual fear or anxiety in several of his young patients. One child, Herbert, was “tremendously frightened by running water, gas burners, and many other things.” He became upset by any change of an accustomed pattern. “If he notices change, he is very fussy and cries.” Another child did a “good deal of worrying.” He was upset because the moon did not always appear in the sky at night. He preferred to play alone and would get down from a play apparatus as soon as another child approached. Insistence on sameness leads children with autism to become greatly distressed when anything is broken or incomplete, and they demand consistency in the sequence of daily events. Kanner noted that although many individuals with autism learn to tolerate changes in routine and interactions with other people in their environment as adults, these interruptions cause a great deal of anxiety in young children with autism. Social interactions with other people are an unwelcome intrusion to the child with autism. When social interaction is forced upon the child, Kanner observed that the child, with a great deal of anxiety, will either ignore the person attempting to interact or quickly answer to end the intrusion. This aspect of autism, although consistently described by parents (Gurney et al. 2006) and included as a feature in the DSM-IV-TR, has not been extensively studied.

Muris and colleagues (1998) examined the presence of co-occurring anxiety symptoms in 44 children diagnosed with autism or pervasive developmental disorder. Using
Parental report, they found that 84.1% of the children met criteria for at least one anxiety disorder. Gillott et al. (2001) compared high-functioning children with autism to two control groups including children with specific language impairment and normally developing children on measures of anxiety and social worry. Children with autism were found to be significantly more anxious on both indices.

**Gastrointestinal Disorders**

Children with autism have a higher incidence of gastrointestinal (GI) problems than typically developing children or children with developmental delays (Valicenti-McDermott et al. 2006). GI problems are a common complaint of parents of children with autism and has been one of the factors that have prompted the use of complementary and alternative medicines (Harrington et al. 2006). A number of clinicians have emphasized the need to investigate GI problems, particularly in low-functioning children who are unable to communicate their distress and for whom alleviation of the GI condition may appreciably improve the quality of life.

**Autoimmune Disorders**

Immune dysfunction may play an important role in a subset of pervasive developmental disorder cases (van Gent et al. 1997). Some patients with pervasive developmental disorder demonstrate abnormalities and/or deficits of immune system function leading to inappropriate or ineffective immune response to pathogen challenge (Ashwood and Van de Water 2004b). For example, children with autism or pervasive developmental disorder often have recurrent infections (Stern et al. 2005), peripheral immune abnormalities (Ashwood et al. 2003, Croonenberghs et al. 2002, Singh 1996), or neuroinflammatory responses in the central nervous system (CNS) (Vargas et al. 2005). In addition to general immune system dysfunction, recent evidence suggests that certain forms of autism are associated with an autoimmune condition (Ashwood and Van de Water 2004a, 2004b). Autoimmunity occurs when the immune system inappropriately identifies and reacts to “self” components. Antibodies produced during an autoimmune response play a critical role in the pathogenesis of several peripheral neurological diseases, including myasthenia gravis, Lambert–Eaton myasthenic syndrome, and neuromyotonia (Lang et al. 2003a, 2003b, Lang and Vincent 2003, Newsom-Davis et al. 2003, Scoppetta et al. 2003). Autoimmunity may also play a role in CNS diseases, notably psychological and neural disorders associated with streptococcus (PANDAS), which accounts for a subgroup of childhood-onset obsessive–compulsive disorders (OCD) and tic disorders (Snider and Swedo 2003). Several studies have also reported that autoimmune disorders are more common in family members of ASD patients compared to typically developing controls. Mothers and first-degree relatives of children with autism are more likely to have an autoimmune disorder (16% and 21%) than controls (2% and 4%) (Comi et al. 1999). Similar results were obtained in a study of autoimmune disorder frequency in families that have children with pervasive developmental disorders, including autism (Sweeten et al. 2003). A recent study of 308 children with ASD reported that regression in autism was significantly associated with a family history of autoimmune disorders (Richler et al. 2006).

Antibodies directed against CNS proteins have been found in the sera of autistic children. Targets of autoantibodies in pervasive developmental disorder patients include neuron–axon filament protein (Singh et al. 1997), myelin basic protein (Singh et al. 1993), serotonin receptor (Todd and Ciaramello 1985), cerebellar neurofilaments (Plioplys et al. 1994), nerve growth factor (Kozlovskaia et al. 2000), alpha-2-andrenergic binding sites (Cook et al. 1993b), and antibodies against the caudate nucleus (Singh and Rivas 2004).

Maternal antibodies to fetal brain tissue may also play a role in a subset of pervasive developmental disorder cases (Vincent et al. 2003). Antibodies from serum of mothers who have children with pervasive developmental disorder have been shown to react to antigens on lymphocytes from their affected children (Warren et al. 1990). Given that antigens expressed on lymphocytes are also found on cells of the CNS, these authors proposed that aberrant maternal immunity may be associated with the development of some cases of pervasive developmental disorder. In support of this, the presence of antibodies against brain tissue was recently identified in the serum of a mother whose child has autism (Dalton et al. 2003). Van de Water and colleagues have identified a common pattern of autoantibody production to fetal brain tissue in the serum of mothers who have two or more children with pervasive developmental disorder (Braunschweig et al., in press). Collectively, these studies suggest that an atypical maternal antibody response directed against the fetal brain during pregnancy may be present in a subset of pervasive developmental disorder cases.

**Developmental and Genetic Mechanisms Implicated in the Etiology of Autism**

There is growing consensus that autism is caused by multiple mechanisms that derail development of the brain (Belmonte and Bourgeron 2006, Freitag 2007, Gupta and State 2007, Happe et al. 2006, Moldin and Rubenstein 2006, Moldin et al. 2006). In this section of the chapter, we address developmental and genetic mechanisms that are likely to participate in susceptibility to autism.

Autism affects boys roughly four-fold more often than girls, a key observation whose mechanism remains a mystery. Based on the concordance rates in monozygotic twins (~60–90%), roughly 10-fold higher than in dizygotic twins and siblings, autism is considered to be the most heritable of neuropsychiatric disorders (Bailey et al. 1995, Smalley et al. 1988). However, it is generally acknowledged that autism is genetically heterogeneous. While a small subset of cases are caused by X-linked, autosomal-dominant, autosomal-recessive, or chromosomal defects, researchers currently believe that many cases are due to more complex genetic mechanisms, including coinheritance of multiple alleles and/or epigenetic modifications (Freitag 2007, Gupta and State 2007). Furthermore, approximately 10% of sporadic cases of autism are associated with de novo copy number variations in either single genes or sets of genes; de novo copy number variations occurred in only ~2% of multiplex cases and 1% of controls (Sebat et al. 2007). The mechanisms that cause these copy number variations are unknown, but paternal age contributes to autism risk (Reichenberg et al. 2006); perhaps increasing age leads to the accumulation of these de novo germline mutations.
The clinical and neuroanatomical features provide boundary conditions for considering the genetic and developmental underpinnings of autism. Autism is probably caused by defects in neural systems that process social information, language, and sensorimotor integration. The components of the neural systems required for these complex behaviors are beginning to be understood, yet much work needs to be done. Neural system lesions can be localized or distributed (Rubenstein 2006). A localized lesion that weakens or disables one component of a circuit can impede the function of the entire circuit, generating a behavioral phenotype. This phenotype can likewise be generated by defects in another component of the same circuit. Thus, related behavioral syndromes can be generated by a variety of anatomical defects.

Distributed lesions can be caused by defects that are common to many regions of a given neural system, or to multiple neural systems. For instance, mutation of a gene that is broadly expressed, such as that causing fragile X mental retardation (FRAXA; FMR1), Rett syndrome (MeCP2), and tuberous sclerosis (TSC1&2), will disrupt neural function throughout the nervous system, weakening neural processes such as synaptic transmission or synaptic plasticity. Localized lesions are exemplified by mutation of genes that are expressed in neurons that share common features (such as neurotransmitter type or participation in a common circuit). For instance, members of the Dlx homeobox gene family (which encode transcription factors) are expressed during development of most forebrain GABAergic neurons, and some Dlx genes are expressed in mature forebrain GABAergic neurons (Cobos et al. 2005). Mutations that simultaneously block the function of pairs of mouse Dlx genes disrupt development of most forebrain GABAergic neurons (Anderson et al. 1997). This has the potential to disrupt the cortex–basal ganglia–thalamus–cortex circuit, through defects in cortical GABAergic local circuit neurons, basal ganglia GABAergic projection neurons, and the GABAergic thalamic reticular nucleus. Furthermore, individual Dlx genes (e.g., Dlx1) are required for function and survival of maturing cortical interneurons; loss of Dlx1 function can result in epilepsy (Cobos et al. 2005). Mutations in the Dlx genes have been detected in autistic individuals, although it is unknown whether these alleles contribute to the disorder (Hamilton et al. 2005).

Developmental defects can alter the connectivity between regions or the function within a given region and thereby derail neural systems. Interregional connectivity defects can be caused by alterations in axon pathfinding and synapse choice. It is not known whether these types of abnormalities are found in autism, although there is evidence for connectivity defects from functional imaging studies (Kana et al. 2006). Below, we briefly review salient information about genes whose functions are linked to autism. We have organized this information according to known functions of these genes, although many of these genes have functions that are not limited to their assigned categories.

**Signal Transduction**

**Tuberous Sclerosis (TSC1&2) and PTEN**

Children with TSC (autosomal dominant) have greatly increased rates of autism (25–50%), epilepsy, and mental retardation (Wiznitzer 2004). TSC1 (hamartin, 9q34) and TSC2 (tuberin, 16p13) encode GTPase-activating proteins that inhibit the activity of the small G-protein Rheb. TSC1/TSC2 are tumor suppressors by reducing activity of mTOR kinase (Inoki et al. 2005). mTOR promotes protein synthesis and other processes that increase cell growth.

TSC1/TSC2 are integral regulators of signal-transduction cascades downstream of signaling pathways that activate receptor tyrosine kinases (Inoki et al. 2005). These signals activate a family of phosphatidylinositol lipid kinases (phosphatidylinositol-3 kinases, PI3K) that in turn activate the serine-threonine kinase AKT, which then represses TSC1/TSC2 (Inoki et al. 2005). TSC1/TSC2 are also regulated by intracellular amino acid concentration and by the ATP/AMP ratio—the end product of this regulation is to promote appropriate levels of protein synthesis and cell size (Inoki et al. 2005).

While TSC patients develop focal CNS lesions (tubers), it is likely that the general function of TSC1&2 in most neurons underlies the autistic symptoms. For example, reduced TSC dosage in hippocampal pyramidal neurons results in increased size of the cell body and dendritic spines (Tavazoie et al. 2005). This is intriguing given the increased size of the brain in some children with autism.

Further clues that implicate this signaling cascade in autism come from the observation that some patients with mutations in the phosphatidylinositol phosphatase (PTEN; 10q23.31) have autism with macrocephaly (Butler et al. 2005). PTEN reduces activity of the PI3K pathway through dephosphorylation of phosphatidylinositol-tris-phosphate. Mice lacking CNS function of PTEN have increased signaling through the serine-threonine kinase AKT, TSC, and mTOR pathway (Kwon et al. 2006). These mutants have enlarged brains that are associated with increased dendritic and axonal arbors and increased dendritic spines and synapses. PTEN mutant mice also exhibit abnormal social behavior, further implicating this signaling pathway in autism (Kwon et al. 2006).

**Met Tyrosine Kinase (MET)**

MET encodes a receptor tyrosine kinase (7q31) that is an oncogene which mediates hepatocyte growth factor signaling. MET plays an important role in neuronal migration in the forebrain and cerebellum, as well as in immune and GI function. Mouse knockout mutants have reduced numbers of cortical interneurons and a hypoplastic cerebellum. Campbell et al. (2006) identified a common functional allele in the promoter region of the MET gene that is associated with autism.

**Control of Translation**

**Fragile X (FRAXA; FMR1)**

Mutations that reduce expression (usually through CGG triplet expansion) of this X-linked gene (Xq27.3) cause mental retardation, and about 30% of these boys have autistic symptoms (Belmonte and Bourgeron 2006). In humans and mice, FMR1 mutants have dendritic spines that have an immature morphology (too long and thin). This may result from the fact that FMR1 encodes an RNA-binding protein whose functions include translation regulation in dendrites. Indeed, activation of metabotropic glutamate receptors...
leads to FMR1-regulated protein synthesis in dendrites. This includes production of proteins, such as PSD-95, that participate in excitatory synaptic transmission (Bear et al. 2004, Todd et al. 2003). Thus, FMR1 functions at least in part through transducing excitatory synaptic signals into changes in the protein constituents that modify synaptic function and structure.

**Synaptogenesis Formation and Function**

**Neuroligins (NLGN3 and NLGN4)**

Neuroligins encode plasma membrane proteins that are implicated in regulating synapse development through binding neurexin proteins (Varoquaux et al. 2006). Specific combinations and splice forms of neuroligin/neurexin proteins can specify whether an excitatory or an inhibitory synapse will form (Chih et al. 2006). In rare cases of autism, mutations in two X-linked neuroligins (NLGN3 and NLGN4; Xq13 and Xp22.33, respectively) have been found (Jamain et al. 2003). Furthermore, a de novo deletion in neurexin1 (NRX1) has recently been identified in a pair of affected siblings.

**SHANK3 (ProSAP2)**

SHANK3 (22q13.3) encodes a protein associated with the postsynaptic density of excitatory synapses and can promote dendritic spine maturation. Rare missense mutations in SHANK3 have been identified in autistic individuals (Durand et al. 2007). Furthermore, this region of chromosome 22 is a site of recurrent deletions in autism (Sebat et al. 2007).

**Neurotransmitters/Neuromodulators**

**Oxytocin and Vasopressin Receptors (OXTR; AVP1a)**

Oxytocin and vasopressin peptides are neuromodulators expressed by neurons in the hypothalamus and the amygdala. These peptides have been implicated in the mediation of certain social behaviors (Young et al. 2005) and the receptors for oxytocin (OXTR; 3p25–p26) and arginine vasopressin 1a (AVP1a; 12q14–15) are associated with autism (Wu et al. 2005, Yirmiya et al. 2006).

**Serotonin Transporter (SLC6A4)**

Serotonin has potent effects on many behavioral and developmental processes. One of the earliest biochemical indications that serotonin metabolism may be altered in autism was the finding of an increase in serum serotonin levels in approximately 30% of individuals with autism (Cook et al. 1993a). Although this is not a specific diagnostic finding, it increases the potential importance that some alleles of the serotonin transporter gene (SLC6A4, SERT; 17q11.2) might be associated with autism (Wu et al. 2005, Yirmiya et al. 2006).

**Ion Channels**

**Calcium and Sodium Ion Channels (CACNA1C, CACNA1H, SCN1A, and SCN2A)**

Missense mutations in the L-type (CACNA1C, Cav1.2; 12p13.3) and the T-type (CACNA1H, Cav3.2) calcium channels have been identified in rare cases of autism (Splawski et al. 2004, 2006). Similarly rare missense mutations have been identified in two sodium channel genes (SCN1A; 2q24; SCN2A; 2q23-2q24.3) (Weiss et al. 2003).

**Metabolic Genes**

**Phenylalanine Hydroxylase**

Historically, the finding that autism is highly associated with phenylketonuria (PKU—hyperphenylalaninemia) was one of the turning points in establishing a biological etiology of autism (Cohen et al. 2005). There are several hundred alleles of phenylalanine hydroxylase (12q23.2) (www.pahdb.mcgill.ca), many of which can cause PKU in the homozygous phenotype. Interestingly, relatively little is known concerning the neuropathology of PKU-associated autism. And, the condition is now relatively rare due to neonatal screening and dietary treatment.

**D7-Dehydrocholesterol Reductase**

**Smith–Lemli–Opitz**

The Smith–Lemli–Opitz (SLO) gene encodes D7-dehydrocholesterol reductase (DHCR7; 11q12–q13); loss of function mutations causes accumulation of D7-dehydrocholesterol. This recessive disorder has broad developmental affects, including autism (Sikora et al. 2006). While SLO is a rare cause of autism, it demonstrates that the more general disruption of cholesterol metabolism, and related pathways, may be one component of the etiologic mechanisms.

**Regulation of Gene Expression**

**Rett Syndrome (MeCP2)**

Rett syndrome is due to loss of function mutations of the methyl-CpG-binding protein 2 (MeCP2; Xq28) (Moretti and Zoghbi 2006). Girls with Rett syndrome commonly exhibit autistic symptoms; males generally die prenatally. Some mutations result in milder symptoms that include autism in both boys and girls. MeCP2 is a nuclear protein that binds to methylated CpG dinucleotides. It recruits a co-repressor complex that is implicated in transcriptional repression. Mouse MeCP2 mutants show subtle increases and decreases in brain gene expression, including reduced ubiquitin protein ligase E3A (UBE3A) and b3 GABA A receptor (Gabrb3); these are imprinted genes in the Angelman’s disease locus. Inheritance of a maternal duplication of this region (15q11.2–q13) is the most commonly associated chromosomal abnormality found in autism (Schwab 2006). MeCP2 mutants also show increased Dlx5 expression, variable effects on brain-derived neurotrophic factor expression, and RNA splicing defects (Moretti and Zoghbi 2006). MeCP2’s association with autism highlights the possibility that epigenetic modifications of chromatin (e.g., cytosine methylation and histone methylation/acetylation) and parent of origin effects (imprinting) may have broader roles in the etiology of autism (Schwab 2006).

**Engrailed2 (EN2)**

Alleles of the En2 homeobox transcription factor (7q36), which regulates cerebellum development, is associated with autism in some studies (Benayed et al. 2005). Mouse mutants exhibit social deficits (Cheh et al. 2006).
Distal-less 2 & 5 (Dlx2 and Dlx5)
Missense mutations of the Dlx2 (2q31.1) and Dlx5 (7q21.3) homeobox transcription factors have also been identified in autistic individuals (Hamilton et al. 2005). These genes regulate development of forebrain GABAergic neurons, and Dlx1 mutations lead to epilepsy in mice (Cobos et al. 2005).

Summary
The array of genes that either cause or predispose to autism speaks to the diversity of genetic and epigenetic mechanisms that can cause this heterogeneous disorder. It seems likely that autism can be caused by an even larger number of genes—perhaps through combinatorial mechanisms involving coinheritance of multiple weak alleles and environmental factors that influence epigenetic state as well as brain development and function. Despite this complexity, some mechanistic themes are beginning to emerge:

1. Defects in molecular pathways that link synaptic and nonsynaptic signals with changes in protein synthesis that can modulate neural response properties (FRMR1, MET, NGLN3/4, PTEN, Shank3, and TSC1/2).
2. Defects in transcriptional regulation of neural genes (DLX2/5, EN2, and McCP2).
3. Defects in neural excitatory state (CACNA1C, CACNA1H, SLC6A4, SCN1A, and SCN2A).
4. Defects in signals within specific neural circuits that can modulate neural response properties (FRMR1, MET, NGLN3/4, PTEN, Shank3, and TSC1/2).

The notion that cortical development may be altered in autism arose initially from clinical observations indicating that the head circumference of children with autism is larger than general population controls. For example, Bailey et al. (1993) found that 37% of their subjects had a head circumference above the 97th percentile (macrocephalic), while Lainhart et al. (1997) found that 14% of autistic subjects had macrocephaly. Fombonne and colleagues (1999) conducted a meta-analysis of published literature and concluded that an average estimate of macrocephaly in autism was 20.6%. These data would suggest that large head and thus brain size might be a common, although by no means universal, feature of individuals with autism.

A number of studies have indicated that cortical development may be altered in autism. Piven et al. (1990) noted malformations of the cortex such as polymicrogyria, but these observations have not been replicated. Piven et al. (1995) were also the first to use a computer-aided assessment system to evaluate the cerebral cortex in adults with autism. They concluded that there were increases in the volumes of the temporal, parietal, and occipital lobes but not of the frontal lobes. Neither Aylward et al. (1999) nor Schumann et al. 2004 observed a difference in total brain volume.

Courchesne and colleagues have published a series of studies that demonstrate abnormal brain growth in autism (Carper and Courchesne 2005, Courchesne et al. 2001, 2003, Redcay and Courchesne 2005). They propose that the brains of children with autism are either of normal size or perhaps slightly smaller than typically developing children at birth. However, the cerebral cortex, and preferentially the frontal lobe, undergoes a rapid and precocious growth (relative to control children) during the first 2 years of life. Subsequently, brain growth plateaus and ultimately the volume of the brains of typically developing children catch up. Thus, in older children with autism, the brain is either the same size or even slightly smaller than typically developing subjects. Importantly, this finding has recently been replicated by the Piven laboratory (Hazlett et al. 2005). This study indicates that precocious brain growth may not begin until near the end of the first year of life and is clearly evident by the second year of life.

Beyond the cerebral cortex, other brain regions have also been found to have an abnormal brain development. Perhaps most striking is the amygdala, a region of the...
temporal lobe that is involved in the detection of dangers in the environment and in modulating some forms of social interaction. Interestingly, the amygdala undergoes a very protracted development in boys (Giedd et al. 1996). It increases in size by nearly 40% between the ages of 8 and 18 years (Schumann et al. 2004). This is striking since the rest of the brain actually decreases in size during this same time period by about 10%. For boys who have been diagnosed with autism, the amygdala demonstrates precocious growth and has reached adult size by 8 years of age.

Many studies have gone beyond simply evaluating the volume of brain regions and have analytically broken the tissue down into compartments representing gray and white matters. There have been some indications that alterations in white matter volumes may actually be a more sensitive indicator of pathology in autism than grey matter differences (Carper and Courchesne 2005, Courchesne et al. 2001, 2003, Herbert 2005, Herbert et al. 2004). In fact, some have proposed that the enlarged brain volume that has been reported can be accounted for, in large part, by disproportionate increases in the volume of white matter. There are reports of greater white matter volumes in boys with autism aged 2–3 years, when compared to controls. Interestingly, this pattern was not found in adolescence, further supporting an abnormal early development. Other analyses of white matter have suggested that those compartments of white matter that develop latest (i.e., the radiate regions that mature late in the first year and into the second postnatal year and beyond) are of greater volume than the earlier maturing sagittal and bridging fibers (Herbert et al. 2003). Recent studies using diffusion tensor-weighted imaging of white matter indicate that in autism regionally specific disruptions of white matter integrity may persist into adulthood (Keller et al. 2007).

To summarize, despite the heterogeneity of findings, a few clear directions are emerging:

1. Autism is clearly not a disorder that affects a single brain region.
2. The kind of brain pathology in a particular individual may depend on the phenotypic characteristics of autism (e.g., presence versus lack of developmental delays) as well as comorbid features of the disorder (e.g., seizures versus no seizures).
3. Finally, the pathology of autism may not be apparent in the mature size and shape of the brain but in the time course of development of both the structure and the connections of the brain.

**Microscopic Neuropathology**

There is no obvious lesion in the brains of individuals with autism. In fact, at first blush the brain looks remarkably normal. One consistent finding in autism has been the lower number of Purkinje cells in the cerebellum (Rito and Garber 1988). When using neural stains that mark cell bodies, there are noticeable gaps in the orderly arrays of Purkinje cells. Whether Purkinje cell loss is due to autism, epilepsy, or the co-occurrence of both disorders is not currently clear. It is also not clear whether loss of Purkinje cells is characteristic of autism or a more general finding in many neurodevelopmental disorders. Thus, cerebellar alterations have been reported in idiopathic mental retardation, Williams syndrome, and many other childhood disorders. There have also been a few reports of alterations of brainstem nuclei, such as the olivary complex, that is connected to the cerebellum (Bailey et al. 1998). These findings might inform the time frame of neural insults responsible for autism, but they are currently based on too few observations to be considered typical of autism.

The cerebral cortex has also been reported to be abnormal at a microscopic level in autism. There have been some published examples of migration defects such as ectopias (Bailey et al. 1998). It has also been proposed that the columnar organization of the cortex in autistic patients is abnormal (Casanova 2006, Casanova et al. 2002). These provocative findings are awaiting confirmation in larger studies using sophisticated quantitative strategies. Finally, the amygdala has been found to have fewer neurons in the mature brain (Schumann and Amaral 2006). Since this study was carried out with cases that did not have comorbid epilepsy, this could be a real component of autistic neuropathology.

**Functional Neuroimaging**

Another approach to establishing which brain regions are most impacted by autism is the use of functional imaging. While this literature is growing rapidly and has provided important insights into the neural impairments of autism, it also applies only to the high-functioning segment of the population who can be compliant with the demands of the behavioral and imaging conditions. Many of the functional imaging studies have focused on brain regions thought to be involved in social function, such as the frontal lobe and amygdala, and on behaviors thought to be selectively impaired in autism, such as perception of social stimuli and theory of mind. Given that more than 400 papers have appeared in recent years dealing with functional imaging of individuals with autism, we only briefly highlight some findings related to the amygdala that, as described above, is clearly pathological in autism. For recent, more extensive reviews of fMRI in autism see Kana et al. (2006) and Just et al. (2007).

The amygdala has been the focus of a large number of functional imaging studies in autism prompted, in part, by the “Amygdala Theory of Autism” proposed by Baron-Cohen and colleagues (2000). Functional neuroimaging studies have indicated that individuals with an autism spectrum disorder show abnormal patterns of amygdala activation in response to social stimuli. High-functioning adults with autism or Asperger syndrome demonstrate deficits in the ability to infer the mental state of another person from viewing images of their eyes (Baron-Cohen et al. 1997). This task activates the amygdala and superior temporal gyrus in control subjects. In contrast, individuals with autism or Asperger syndrome activate the frontotemporal regions but not the amygdala when performing this task (Baron-Cohen et al. 1999). Pierce et al. (2001) found that the amygdala was activated when typically developing individuals viewed unfamiliar faces, but the amygdala was not activated in individuals with autism during this task. Children and adolescents with autism spectrum disorders show abnormal amygdala activation while matching faces by emotion and assigning a label to facial expressions (Wang et al. 2004). While children in the control group showed more amygdala activation when matching faces by emotion than assigning a verbal label, the children with autism spectrum disorders did not demonstrate this pattern of task-dependent amygdala modulation.
One caveat to interpreting findings from face processing studies is that subjects with autism are reluctant to make eye contact, and there is some controversy as to whether they are actually examining the face in a similar manner as controls (Davidson and Slagter 2000). In fact, when viewing faces, patients with autism show abnormal visual scan paths during eye-tracking studies, typically spending little time on the eyes (Klin et al. 2003, Pelphrey et al. 2002). Whether these findings represent active avoidance of the eye region, potentially involving the amygdala, or a more global lack of social interest or motivation is unclear. An emerging hypothesis is that the amygdala may play a role in mediating or directing visual attention to the eyes (Adolphs et al. 2005, Grelotti et al. 2005, Schultz 2005).

Research from typically developing children indicates that children who are physiologically aroused by a distressing film were more likely to avert their gaze from the stimulus. It is plausible that children with autism utilize a similar strategy of gaze aversion in response to arousing social stimuli. Given the amygdala’s role in fear and anxiety, one would predict heightened amygdala activation during eye contact in persons with autism if they found the eye contact aversive. Dalton and colleagues (2005) found that the amount of time persons with autism spent looking at the eye region of the face was strongly positively correlated with amygdala activation, but this was not the case in control subjects. The autism subjects also showed greater left amygdala activation relative to controls in response to unfamiliar faces and greater right amygdala activation in response to both familiar and unfamiliar faces. This suggests a heightened emotional, or even fearful, response when autistic individuals look at another person’s eyes, regardless of whether they are familiar or a stranger. Nacewicz et al. (2006) recently found that individuals with autism (8–25 years of age) who had a smaller amygdala were also slower to distinguish emotional from neutral expressions and showed least fixation on the eye regions of the face. These same individuals were also the most socially impaired in early childhood.

Recently, Ashwin et al. (2007) found that during the perception of fearful faces, Asperger syndrome patients showed less activation in the left amygdala relative to controls. However, these results may again be due to the abnormal way in which individuals with autism view faces. Spezio et al. (2007a, 2007b) confirmed that participants with autism show less fixation on the eyes and mouth, but also a greater tendency to saccade away from the eyes when information was present in those regions. This study provides insight into the aberrant manner in which people with autism view faces, which likely influences face processing and subsequent functional imaging study results. Additional studies would benefit from measuring the physiological responses associated with arousal and anxiety (i.e., increased heart rate, skin response, etc.) during face processing in individuals with autism.

**Behavioral Treatment**

Early on in autism treatment two main treatment approaches dominated the literature: treatment based on a psychodynamic conceptualization of autism (e.g., Bettelheim 1967) and treatment based on the application of Skinnerian models of learning. The first empirically supported paper came from the latter tradition. In 1964, Wolf and colleagues (1964) published the first single subject design of the application of behavioral principles to the symptoms of a young child with autism. The treatment was carried out virtually all day, every day, for several years in an institutional setting. The child eventually returned to his/her home, with greatly improved behavior, language, adaptive, and cognitive abilities. The teaching procedures involve massed trial teaching, and many of the core approaches to teaching are still in use today (Leaf and McEachin 2001, Lovaas 1981).

The view that autism was a neurobiological disorder, championed by Bernard Rimland (1964), had fundamental effects on treatments. Gradually, autism became viewed as a developmental disorder, like mental retardation, for which rehabilitation (or, more exactly, habilitation) was the appropriate approach. Then, the passage of public law 94–142 in 1975 mandated appropriate free public education for all children with disabilities and cast tremendous responsibility on school districts for appropriate education and habilitative services.

**Main Intervention Approaches**

Three main philosophies guided the development of interventions. One strategy involved the continued application of learning theory to reduce behavioral deficits and to decrease behavioral excesses (Wolf et al. 1964). These strategies, under the umbrella of applied behavior analysis, were applied in two basic forms. The first involved massed trials with high levels of adult control and direction of the teaching (Lovaas 1987, McEachin et al. 1993). A more naturalistic application of learning principles capitalized on children’s own interests, preferences, and initiatives to assure high levels of motivation for learning. These approaches are best described in two well-known models: incidental teaching, first applied to autism by McGee et al. (1983, 1991), and pivotal response training, as developed by Schreibman and Koegel (Koegel et al. 1988, Schreibman and Pierce 1993, Williams et al. 1981).

A second main approach was the TEACCH model of intervention (Schopler et al. 1984, 1995). This capitalized on teaching by directing tasks to children’s visual–spatial skills, focused on developing skills for independent work and independent functioning, minimized the need for ongoing social instruction and verbal instruction, used visual communication systems to supplement verbal instruction, built a great deal of repetition and routine into the organization of the teaching, and reduced the sensory complexity of the environment to maximize attention. This approach also focused on parents as primary deliverers of child interventions.

The third main approach focuses on autism as a developmental deficit. This approach takes as a premise that early compromises in social–communicative development have increasingly large downstream effects that impair the development of triadic relations (Meyer and Hobson 2004, Rogers and Pennington 1991, Sigman and Capps 1997). The developmental approaches have flourished and some of the better-known current models include Greenspan and Winters’ floortime approach (Greenspan et al. 1997), Gutstein’s relationship development intervention (Gutstein 2005), the Denver model (Rogers and Lewis 1989), and the SCERTS model (Prizant et al. 2006). These approaches strongly emphasize the quality of the relationship between child and teacher and child and parent, use a child-centered approach based on following children’s interests and initiatives, and strongly emphasize progress in social communication skills.
A fourth treatment orientation focuses on the sensory and motor differences characteristic of autism. Some practitioners think that the sensory differences in autism are the primary impairments, with the social, communicative, and behavioral abnormalities resulting from the intense distress or confusion that the sensory impairments cause (reviewed in Baranek 2002). Occupational therapists have led the way in evolving treatments targeted at sensory deficits in autism.

**Treatment Delivery**

Behavioral treatments may be delivered to change very targeted symptoms. Virtually all the main symptoms of autism have been demonstrated to be modifiable with targeted treatments (Schreibman 2005). Two very important attributes of this literature deserve mentioning. First, positive treatment outcomes for targeted skills have been documented across the entire age range and functioning range for persons with autism spectrum disorders. The second important point is that the techniques used have changed considerably over the years. The use of aversive consequences has largely disappeared, as the field has become more sophisticated in the application of reinforcement strategies (Carr et al. 2002, Horner et al. 2002, Howlin 1998, Lalli et al. 1995). It is now clear that autism is treatable.

The current science of early behavioral intervention in autism is targeting several main research questions: (1) Is "recovery" possible for more than an occasional child? (2) Are some treatments more effective than others? (3) What are the "active ingredients" of effective comprehensive treatments? (4) What child, family, programmatic, and environmental variables mediate and moderate early intervention outcomes? (5) Can we identify an aptitude by treatment interaction in autism that will allow us to know which subgroups of children with autism will respond best to which treatment approach or treatment elements?

We still have no randomized controlled trials that compare the best-known comprehensive approaches. The few randomized controlled trials that exist have consistently demonstrated that well-planned and carefully delivered treatments, both developmental and behavioral, improve children's functioning, particularly IQ and language abilities, compared to no treatment, both over the shorter term and over the longer term (Jocelyn et al. 1998, Smith et al. 2000). The fact that IQ and language are so responsive to high-quality treatment delivered in the preschool period is quite promising, since these are the best predictors of outcomes over time in autism (Howlin 2005). Given the findings from other models thus far, it is likely that a carefully planned intensive and comprehensive intervention with expert delivery will result in positive gains for children compared to a no-treatment condition.

Comprehensive intervention for older children occurs every day in classrooms across America, but these have not received the scrutiny of early intervention approaches. While some classrooms for older children also follow a very specific educational model, it is probably more often the case that public schools use a variety of teaching methods to teach the individual educational objectives that guide each child's special education in the public schools. Two areas of research in this group involve the development of social skills, especially for children with milder symptoms (Ozonoff and Miller 1995, Simpson et al. 1997, Wooten and Mesibov 1986), and the questions about inclusive education (Janney and Snell 1997, Kellegrew 1995, Simpson and Smith Myles 1993).

**Other Treatments**

**Psychopharmacological Treatments**

Given the lack of specific brain or neurotransmitter systems as a target for pharmacological treatment, currently there is no psychopharmacological treatment that is directed at the core symptoms of autism (Palermo and Curatolo 2004). The atypical antipsychotics (olanzapine, ziprasidone, quetiapine, and aripiprazole) have shown some efficacy in improving certain behavioral symptoms of AD such as aggressiveness, hyperactivity, and self-injurious behavior (Stachnik and Nunn-Thompson 2007). Weight gain and sedation are frequently reported adverse consequences of these treatments. Risperidone has become the first approved drug for treatment of autism. Previously risperidone was studied as off-label medication to treat autism because of its increased safety and efficacy over conventional neuroleptics. Risperidone can be used as a potentially safe and effective treatment for disruptive behavioral symptoms in children with autism (West and Waldrop 2006). The long-term use of these drugs in conjunction with the plethora of other alternative medications that are being used require additional analysis pertaining to safety (McCracken 2005).

**Complementary Alternative Medicine Treatments**

It would be fair to say that in no area of developmental pediatric practice is there more controversy than in the selection of treatments for children with ASDs. An increasing number of complementary and alternative medical therapies are often tried because they are perceived as treating the cause of the children's symptoms (Levy and Hyman 2005). Current treatments range from various forms of restricted diet (Millward et al. 2004) to hyperbaric oxygen treatment (Rossignol 2007) to a variety of vitamin and mineral supplements (Hanson et al. 2007). Secretin provides a good example of how an incidental perception of behavioral improvement following treatment leads to widespread clinical use despite little or no scientific rationale for the therapy. And even despite nearly unanimous negative results in placebo-controlled clinical trials (Esch and Carr 2004), there still remains substantial parental interest in attempts at using secretin as one potential therapy. In many respects, this speaks to the desperate need of parents and practitioners alike to obtain more scientifically based approaches to the therapy of both the core and the comorbid symptoms of autism.

**Conclusions**

Autism is a spectrum disorder that is defined behaviorally as consisting of social and communication impairments and the presence of stereotyped behaviors and/or circumscribed interests. There is a general consensus that autism has a variety of etiologies that consist of different proportions of genetic and environmental contributions. While some 10% of autism cases are associated with a defined medical condition such as fragile X syndrome, the cause(s) of the remainder of idiopathic autism are currently unknown.
Various behavioral therapies based on the operant conditioning literature are valuable for eliminating unwanted behaviors and bolstering language, social interaction, and pragmatic life skills. Autism affects the development of several brain systems. The most common biological finding is precocious brain development of the cerebral cortex and amygdala. However, the neuropathology of autism is still at a very early stage of understanding and both additional structural MRI and postmortem studies are needed to better define the neural systems involved. Beyond the nervous system, there appears to be a variety of dysregulated functions in the immune system of some individuals with autism and some mothers of individuals with autism. Whether the immune dysregulation is a cause or effect of autism remains to be determined. Finally, autism is generally agreed to be a polygenic disorder, with multiple genes showing weak association. This may be a reflection of the fact that better phenotyping of autism subtypes is essential before fruitful genotyping can be accomplished.

Introduction
As a syndrome characterized by incapacitating cognitive decline, dementia is easy to define in general terms but difficult to pin down with categorical precision. Although recognized in ancient times, the term “dementia” was first introduced in 1789 by Phillipe Pinel, and indeed it was 19th century clinicians who first grappled with its defining features. Pinel’s student Jean Esquirol, for example, divided the dementias into acute, chronic, and senile forms, and his characterization of senile dementia is a remarkably accurate description of what came to be known as Alzheimer’s disease (AD). Senile dementia, he maintained, begins with “enfeeblement of memory” particularly the memory of recent events. Over time, dementia progressed to include difficulty in comprehension and attention and a diminishment of “will.”

Recapitulating many of these earlier descriptions, in its current usage dementia requires three defining features. First, the decline should exist across multiple cognitive domains, typically including memory plus another domain such as language, visuospatial ability, or executive function; second, cognitive decline should emerge chronically, not acutely; and third, cognitive decline should be sufficiently profound to impair patient’s day-to-day function. Accordingly, a syndrome that presents with impairments in a single cognitive domain is not dementia but rather defined according to its selective domain—for example, amnesia, aphasia, or attention deficit disorder. A syndrome that presents acutely might be labeled delirium, not dementia.

As with any attempt at developing a categorical definition, the difficulty is at the boundaries of the definition. Two points in particular have been most problematic and are still matters of debate. The first is the requirement that memory per se represent at least one of the impaired cognitive domains. For example, diseases that spare the medial temporal lobes might present early on with relative little memory dysfunction, but nevertheless target multiple cognitive domains and by all accounts are dementing illnesses. A second and perhaps more problematic point of debate is the requirement that the cognitive decline have a significant impact on daily function. Not only are functional deficits difficult to quantify, but early stages of many dementing illnesses cause subtle defects. Whether these defects actually impair a patient’s function depends very much on the cognitive challenges of an individual’s daily life.

With a greater understanding of the neuroanatomical correlates of cognition, and with techniques that can directly assess the functional integrity of these brain regions, an anatomical definition of dementia is beginning to supplant antiquated and categorically elusive definitions. Specifically, dementia can be defined as a progressive disorder that begins in one cortical region and over time spreads to involve multiple cognitively important sites. Beyond the advantage of relying on more objective measures, an anatomical definition of dementia is useful when attempting to distinguish among the different causes dementia. In principle, abnormalities in four general processes can cause dementia—infestations (such as syphilis); “metabolic” deficiencies (such as B12 thyroid hormone deficiencies); structural lesions (such as neoplasm, hemorrhage, and stroke); and neurodegeneration. Diagnostic tests currently exist for the first three categories, but not for neurodegeneration. Furthermore, reflecting the diminished incidence of tertiary syphilis, the greater awareness and early treatment of vitamin and hormonal deficiencies, and the widespread availability of brain imaging, the vast majority of patients who present to a dementia clinic end up having neurodegeneration. In practice, therefore, distinguishing among the different types of neurodegeneration (Table 24–1) is the typical diagnostic dilemma facing the clinician. These disorders are different because they target separate regions of the brain, particularly early in the disease process, and therefore mapping the anatomical sites of dysfunction is currently the most effective method for accurately diagnosing the most common causes of dementia.

Importantly, since most neurodegenerative processes spread over time, mapping differential anatomical patterns is best achieved during the early phases of the disease. In contrast to other diseases, such as stroke for example, currently there are no definitive markers of regional disease.
caused by neurodegeneration. A patient’s map of cortical dysfunction, therefore, usually emerges as a composite from three sources of information. A detailed history of symptoms and a careful exam, including cognitive testing, will typically offer first clues about affected sites. An extensive neuropsychological battery of tests will provide additional information in localizing the neurodegenerative lesions. Finally, information from brain imaging can sometimes contribute in mapping sites of dysfunction. As a general point, despite the justifiable enthusiasm engendered by brain imaging, the current diagnostic utility of these techniques is still under investigation. Currently, conventional MRI, typically ordered to rule out structural lesions, occasionally shows focal patterns of atrophy which can aide in the diagnostic process. Functional imaging techniques that map basal metabolic defects (e.g., positron emission tomography, which assesses basal glucose uptake or single-photon emission computerized tomography, which assesses basal blood flow) are sometimes ordered to help distinguish frontotemporal degeneration from AD.

Beyond its diagnostic value, a focus on the anatomy of neurodegeneration holds promise in expanding our understanding of underlying molecular mechanisms. To date, as discussed in the sections below, most molecular insight into neurodegeneration has come from a focus on protein aggregates (e.g., amyloid plaques, neurofibrillary tangles, or Lewy bodies) or from a focus on genetic polymorphisms that either cause disease or contribute to its risk. With the introduction of techniques capable of profiling gene expression levels, a focus on brain tissue itself is expected to offer additional molecular clues. To maximize the yield of this approach, it has therefore become imperative to first pinpoint the anatomical sites most vulnerable to a neurodegenerative process (Lewandowski and Small 2005).

Because of the foregoing discussion, in this chapter we will focus almost exclusively on neurodegenerative causes of dementia (Table 24–1). Instead of just offering a brief description of each item on this long list, we will provide an in-depth discussion on a select few. Those chosen reflect diseases that are most common and/or those in whom the greatest scientific discoveries have been made, highlighting general principles applicable to all neurodegeneration.

**Alzheimer’s Disease**

One hundred years ago, Alois Alzheimer examined the brain of Auguste D., a demented woman who began developing cognitive deficits in her late 40s, and thereby established that dementia can be associated with neurofibrillary tangles and amyloid plaques (Alzheimer 1907). In 1910, Emile Kraepelin defined “Alzheimer’s disease” as a distinct dementing illness, which, he maintained, provided evidence that dementia can have an “organic” etiology. Yet, for decades thereafter, the major dementia of late life was either dismissed as the inevitable endstage of normal aging or else attributed to “cerebral atherosclerosis.” Over 50 years would pass before investigators began appreciating that late-onset (“senile”) dementia and early-onset (“presenile”) AD are phenotypically indistinguishable under the microscope, prompting the unification of the disorders under the same name.

Nevertheless, despite a shared name and overlapping features, the early-onset and late-onset forms of AD are epidemiologically and etiologically distinct. The early-onset form is extremely rare and is caused by monogenic defects that follow an autosomal dominant pattern. Like other autosomal dominant diseases, early-onset AD has proven amenable to linkage analysis, and many pathogenic mutations have been isolated. In contrast, late-onset AD, which typically manifests after the sixth decade, accounts for over 95% of all cases and has a complex etiology. Like other complex disorders, the cause of late-onset AD has been difficult to pinpoint. Indeed, the late-onset form has historically been called “sporadic” AD to reflect the elusiveness of its etiology. Not only is late-onset disease the more common form of AD, but with increased longevity, late-onset AD has emerged as one of the most common disorders of the brain.

**Clinical Features and Anatomical Profile**

Alzheimer’s disease is, by far, the most common cause of dementia. Typically, AD follows a predictable cognitive course, which has mapped the disease’s anatomical progression. At the gross anatomical level, AD begins by targeting the hippocampal formation, accounting for the fact that during its earliest stages AD presents with hippocampal-dependent memory decline—i.e., difficulty learning new names, place, or events. The hippocampal formation itself is made up of multiple subregions, and AD targets the pyramidal neurons of the entorhinal cortex and CA1 subfield, with relative preservation of the granule cells of the dentate gyrus. From the hippocampal formation, AD typically spreads in a serial fashion to involve other neocortical sites: Dysfunction in the temporal lobes causing language defects, dysfunction in the posterior parietal lobes causing visuospatial defects,

and finally, later in the disease, frontal lobe dysfunction, manifesting as defects in executive function and personality.

Pathology and Pathogenesis
As first described by Alzheimer himself (1907), AD is characterized by two abnormal protein aggregates—extracellular amyloid plaques and intracellular neurofibrillary tangle. The molecular characterization of these aggregates was only established in the 1980s, when the appropriate biochemical and molecular tools became available.

Glenner and Wong (1984) first isolated amyloid plaques from the meninges of patients with AD, and establishing that Aβ peptide is its core constituent. Then, in a succession of molecular discoveries, this peptide was found to be a cleaved product of the amyloid precursor protein (APP), and the enzymes that cleave APP were identified (Hardy and Selkoe 2002). Transgenically engineered mice, expressing mutations that lead to accelerated Aβ production and plaque deposition, have become an important extension of these discoveries, shedding light on the cell biology of amyloid processing and informing on its mechanisms of toxicity.

Two enzymatic steps liberate Aβ from APP. In the first, “β-cleavage” step, BACE (β-APP cleaving enzyme) cleaves APP at or near the N-terminus of the Aβ peptide. Then, in the second, or “β cleavage” step, the APP fragment is cleaved by the β-secretase, a multimeric complex thought to be made up of an essential quartet of transmembrane proteins—presenilin 1 (or 2), nicastrin, APH1, and PEN2. Amyloid plaques themselves are manufactured by Aβ peptide in an assembly line of chemical events. Single monomeric peptides bind together to form oligomeric strings, which bind to form fibrillar sheets, and multiple fibrils bind to form the backbone of the amyloid plaque ensnaring other macromolecules along the way. Thus, Aβ exists in different molecular species—monomers, oligomers, protofibrils, fibrils, and plaques. Operationally, these Aβ species can be dichotomized into monomers, oligomers, and protofibrils, which are soluble, versus fibrils and plaques, which are insoluble when exposed to conventional proteases. Not just a biophysical distinction, the soluble versus insoluble dichotomy have become important in the debate about Aβ neurotoxicity. Earlier cell culture studies suggested that the insoluble species of Aβ are toxic to neurons. One of the main contributions of transgenic mouse models of AD has been to correct this mistake, establishing that it is the soluble species of Aβ that in fact represent the key neurotoxin in the APP pathway.

With respect to neurofibrillary tangles, Tau had been identified as a protein involved in microtubule assembly (Weingarten et al. 1975). Its identification as the central component of the tangles was made through antigenic analysis (Brion et al. 1985), through protein purification methods (Grundke-Iqbal et al. 1986), and eventually through direct sequencing of the isolated pair helical filament peptides (Goedert et al. 1988). Tau protein in the tangles was shown to be highly phosphorylated which was widely believed to underlie its abnormal deposition. Of great importance in our understanding of the pathogenesis of tangles has been the dissection of the etiology of FTDP-17 (see below).

Elucidating the molecular pathways leading to the formation of amyloid plaques and neurofibrillary tangles, however, did not clarify a long-standing debate about whether the Aβ or tau pathway plays a pathogenic role in the disease process. This question was finally resolved when the genetic mutations that cause the early-onset form of the disease were identified (Goate et al. 1991). All the mutations were found to modify the metabolism of APP, with little effect on tau or neurofibrillary tangles, suggesting that the Aβ pathway is pathogenic in AD (Hardy and Selkoe 2002). Thus, although the monogenic early-onset form is extremely rare, this finding has clarified the pathogenic mechanism for all forms of the disease.

Diagnosis and Treatment
When an elderly patient presents with dementia the clinical diagnosis of “probable” AD is made when (a) the history of the illness suggests a slowly progressive process that begins with hippocampal-dependent memory complaints; (b) other illness have been ruled out (i.e., blood tests to rule out B12 deficiency, hypothyroidism, and syphilis, and brain imaging to rule out large strokes, tumors, or bleeding); and (c) when neuropsychological testing identifies in addition to hippocampal dysfunction in other cognitive domains. Imaging studies can strengthen the diagnosis. Specifically, structural MRI might reveal localized atrophy in the medial temporal lobes; or functional imaging studies might reveal dominant hypometabolism in these posterior parietal lobes or medial temporal lobes. Currently, the diagnosis of “definite” AD can only be made when brain tissue is examined, showing a sufficient degree and distribution of amyloid plaques and neurofibrillary tangles.

During the earliest stages of the disease, when the disorder is restricted to the hippocampal formation, AD causes mild forgetfulness and, by definition, is in its predementia stage. Although its precise time course is undetermined, the predementia stage of AD can last many years. Currently, it is impossible to diagnose predementia AD with sufficient accuracy, hampered primarily by the fact that normal aging itself targets the hippocampal formation. With the anticipation that effective drugs will soon be developed, improving the diagnosis of predementia AD has become an important goal. Three diagnostic approaches are currently under investigation: chemical profiles of blood or CSF, cognitive profiles as assessed by neuropsychological testing, and imaging techniques that rely on indicators of neuronal dysfunction or neuronal loss, or indicators of amyloid plaques and neurofibrillary tangles.

Currently, three acetylcholinesterase inhibitors have been approved by the FDA for the treatment of AD dementia—donepezil (Aricept), rivastigmine (Excelon), and razzadine (Reminyl). Most recently, the glutamate receptor blocker memantine (Namenda) has also been approved. In the best case, these drugs slow disease progression, but do not halt its progression or reverse the disease process. Although large-scale studies have demonstrated that these drugs have a statistically significant effect over placebo, whether the effect is clinically meaningful remains a matter of debate. Put into historical context, these relatively safe drugs should be considered “first generation” pharmacological agents, offering therapeutic options whereas only a decade or so ago there were none. Although it is reasonable to consider these drugs for AD patients, it is widely acknowledged that drugs with greater efficacy are urgently needed.
Genetics

Genetic analysis of families with AD showed that some families did show linkage to chromosome 21 markers (Goate et al. 1989), but that the disease was genetically heterogeneous (Schellenberg et al. 1988, St. George-Hyslop et al. 1989). At this time, Levy et al. (1990) had shown that the Aβ was deposited in the blood vessel walls in hereditary cerebral hemorrhage with amyloidosis, Dutch type, (HCHWA-D) (Van Duinen et al. 1987): Van Broeckhoven et al. (1990) and Levy et al. (1990) showed that an APP mutation underpinned this disorder. With this background, focused sequencing of the APP gene in those Alzheimer families that showed evidence for genetic linkage to chromosome 21, identified APP mutations (Goate et al. 1991). The precise positions of these mutations showed that their most likely effect was to alter APP processing (Hardy 1992). More recently, APP duplications in families with a variant of AD have indeed been discovered (Rovelet-Lecrux et al. 2006) and this, together with the absence of AD in Down’s syndrome who were trisomic distal of the APP locus (Prasher et al. 1998), clearly shows that APP overexpression can be a cause of the disease.

In general, families with APP mutations have a typical AD phenotype, although some mutations, including the APP duplications, have a phenotype reminiscent of HCHWA-D (Levy et al. 1990). The age of onset of cases with APP mutations is typically in the late 40s to mid-50s. Cases with APP mutations and Down’s syndrome cases can have Lewy bodies (see below) as well as tangles (Lantos et al. 1994).

The majority of families with autosomal dominant AD did not have APP mutations. Schellenberg et al. identified linkage to chromosome 14 (1992) and Sherrington et al. (1995) identified presenilin 1 as the major locus underlying early-onset autosomal dominant disease. Genetic analysis had shown that a group of German families from Russia (the Volga Germans) did not show linkage to chromosome 14 markers, but rather showed linkage to chromosome 1 markers. A homologue of presenilin 1, presenilin 2, mapped to this region and was shown to underlie the remaining few cases of autosomal dominant disease (Levy-Lahad et al. 1995). In general, cases with presenilin 1 mutations also have typical AD with an age of onset in the late 30s to mid-40s though some cases present with spastic paraparesis and have unusual “cotton wool” plaques (Crook et al. 1998). Cases with presenilin 2 mutations also have features similar to typical AD, but the onset ages are more variable, even within a family (Bird et al. 1989). Cases with presenilin mutations also frequently have Lewy body pathology (Lippa et al. 1998) (see below).

Progress identifying risk genes for sporadic late-onset Alzheimer’s has, not surprisingly, been slower. Corder et al. (1993) identified apolipoprotein E4 as a risk factor and another common variant, apoE2, as negatively associated with the disease. They appear to account for about a third of the population attributable risk for developing AD. However, the mechanism behind this association remains unclear, with most authorities suspecting a role in amyloid deposition (Holtzman 2004). Despite extensive work, no other genetic risk factors for late-onset disease have been validated (Bertram and Tanzi 2004)

Frontal Temporal Dementia

Whereas in the past frontal temporal dementia (FTD) was used synonymously with Pick’s disease, according to current nosology FTD encompasses multiple dementing illnesses, including corticobasal ganglionic degeneration (CBGD) and progressive supranuclear palsy (PSP). As implied by the name, FTD and its variants are unified anatomically by targeting the frontal and lateral temporal lobes, with notable sparing of the medial temporal lobes including the hippocampal formation. Furthermore, at the histological level, FTD and its variants are typically characterized by neuronal inclusions that stain positive for tau or ubiquitin.

Clinical Features and Anatomical Profiles

FTD subtypes are organized according to whether the patient presents with personality and behavioral changes or whether the patient presents with language-predominant dysfunction. Anatomically, the first subtype, historically termed Pick’s disease but currently called frontal variant FTD, targets the prefrontal cortices. In accordance with the functional roles served by the dorsolateral or the orbitofrontal regions of the prefrontal cortex, this subtype of FTD presents with a range of behavioral changes. When the orbitofrontal site is the primary target, patients present with disinhibition, poor impulse control, irritability, aggressiveness, violent outbursts, and mood swings. Dysfunction in the dorsolateral regions manifests with social withdrawal and apathy (often misdiagnosed as depression), loss of will (abulia), and loss of personal or social awareness. Of course, both prefrontal sites might be involved in inappropriate social behavior (i.e., sexual overtures or racially insensitive comments, urination in public, altercations, etc.) are common, as are stereotyped behavior, such as perseverative speech or activities. Changes in eating patterns or religious feelings, obsessive or compulsive behavior, delusions, and hypomania are also part of the syndrome.

After beginning in the prefrontal cortices, this subtype can spread anatomically. When spreading to involve the primary motor cortex or even the spinal cord, a clinical picture of motor neuron disease (MND) manifests. If spreading occurs to the midbrain and the tracts regulating eye movements, a clinical picture of supranuclear palsy (PSP) emerges.

The language subtype of FTD, called primary progressive aphasia (PPA), is further subdivided according to whether the aphasia is fluent or nonfluent. Progressive nonfluent aphasia begins in or around Broca’s area in the frontal lobes, and occasionally will spread to the basal ganglia, in which case this subtype is called CBGD. The fluent aphasia subtype is called semantic dementia, because it is characterized by semantic paraphasias and forgetfulness primarily for words and word meanings. This subtype targets the left lateral temporal lobes.

Pathological Features and Pathogenesis

The underlying histopathology of FTD is variable, with essentially three forms recognized so far, each of which can occur in the context of either familial or sporadic disease: the first is tau pathology, which manifests as tangles, wispy tau filaments or Pick bodies; the second is ubiquitin inclusions; and the third is neuronal loss in the absence of identified histopathology (Forman et al. 2006). These three pathological entities map onto different genetic entities, and while the view we present here may be over simplified, it allows a
convenient presentation of our knowledge in this complex area.

**Diagnosis and Treatment**

When an elderly patient presents with dementia the clinical diagnosis of “probable” FTD is made when (a) the history of the illness suggests a slowly progressive process that begins with complaints that localize to anterior cortical sites; (b) other illness have been ruled out (i.e., blood tests to rule out B12 deficiency, hypothyroidism, and syphilis, and brain imaging to rule out large strokes, tumors, or bleeding); and (c) when neuropsychological testing suggests dominant dysfunction in the frontal lobe or anterior temporal lobe, and relative preservation in hippocampal-dependent tasks. Imaging studies can strengthen the diagnosis. Specifically, structural MRI might reveal localized atrophy in the frontal lobes or the anterior temporal lobes; or functional imaging studies might reveal dominant hypometabolism in these same brain regions. Currently, the diagnosis of “definite” FTD can only be made when brain tissue is examined, typically showing either/or tau-positive or ubiquitin-positive inclusions.

Clinical signs and symptoms can further speciate FTD into its different subtypes: Basal ganglia dysfunction suggests either CBGD or progressive supranuclear palsy; midbrain dysfunction, notably impairment in downward gaze suggests supranuclear palsy; upper or lower motor neuron dysfunction suggests FTD-MND (motor neuron disease); dysfunction to language areas suggests PPA or semantic dementia.

Currently, there are no drugs that are approved for treating the primary process in FTD. Symptomatic treatment is often used, such as neuroleptics or anxiolytics, to allay the behavior manifestations of the disease.

**Genetics**

Several genetic linkages have been reported for which the precise genes have not been identified. In this chapter we will not discuss these, not least because, in the past, some of these genetic linkages have not been confirmed. With this background, we will discuss the three known genes, MAPT (tau), PGRN (progranulin), and CHMP2B because these genes correspond to the three pathologies: tau pathology, ubiquitin inclusions, and no distinctive histopathology (Hardy et al. 2006). However, there are certainly other genes to be found for these syndromes.

Wilhelmsen et al. (1994) identified linkage to chromosome 17 in a kindred with a dementing syndrome. Over the next few years, other kindreds, with very variable dementing phenotypes were described to ostensibly be linked to the same locus, and a 1996 consensus meeting (Foster et al. 1997) facilitated the description of this syndrome as FTDP-17. The linkage region contained the tau gene and Spillantini et al. (1998) pointed out that the majority of kindreds had variable tau pathology. In fact (and confusingly), the PGRN gene is only 1 Mb away from the MAPT gene and the exceptions to these statements turned out to have PGRN mutations (Baker et al. 2006).

Hutton et al. (1998) and Poorkaj et al. (1998) identified mutations in the MAPT gene that caused the syndrome. The known function of tau is to bind microtubules, and tau exists in two classes of isoforms: those with 3 microtubule binding domains, and those with 4. These classes of isoforms are generated by alternate splicing of exon 10. One set of mutations alters splicing control and causes only the 4 repeat isoforms to be generated and the other mutations are point mutations which either disrupt microtubules binding or initiate tau aggregation. In general, those mutations that affect splicing lead to the deposition of wispy filaments consisting of 4 repeat tau; those missense mutations that are in exon 10 lead to heavy deposits of only 4 repeat tau as typical neurofibrillary tangles; and those that are elsewhere in the protein (in exons 9, 11, 12, and 13) usually lead to deposition of typical neurofibrillary tangles consisting of both 3 and 4 repeat tau, although some of these latter lead to the deposition of 3 repeat tau as Pick bodies. Interestingly, two mutations have been found in exon 1 which had been postulated to play a role in the control of tau binding to microtubules and these lead to the deposition of 4 repeat tau tangles.

These general principles connect the genetics to the histopathology of the disorder, but there is presently little understanding of the relationship between the precise clinical features of the disease (which are very variable) and either the genetics or the pathology (though see below). By definition, FTDP-17 is an autosomal dominant disorder. However, its clinical and pathological features overlap with sporadic PSP, sporadic corticobasal degeneration and sporadic Pick’s disease, and it is perhaps worth thinking of these diseases as being separated from FTDP-17 by an accident of nosology.

On close examination of the MAPT gene in Europeans, it was noted that there were two haplotype clades in this population: H1 and H2 (Baker et al. 1999). It is now known that these clades are separated because of a genomic inversion which prevent recombination between them (Stefansson et al. 2005). Only the H1 clade is present in non-Europeans. About 60% of Western Europeans are H1 homozygotes, but >95% of those who have either sporadic PSP or CBD are H1 homozygotes, indicating that MAPT is a risk factor locus for the disease (Baker et al. 1999), and suggesting that genetic variability in tau expression or splicing must underlie this association. In these diseases, the predominant tau species deposited is 4 repeat tau, and furthermore, more detailed analysis of the MAPT locus and tau expression has shown that the risk haplotype is associated with both slightly increased tau expression (~10%) and slightly increased production of the 4-repeat isoform (~20%) (Myers et al. 2006).

**Ubiquitin Inclusions: FTDP-17 without Tau Pathology**

As noted above, a significant proportion of kindreds which showed linkage to chromosome 17 markers did not have mutations in the MAPT locus and these same cases did not have any tau pathology. These cases were first thought to have no distinctive pathology, but careful examination revealed that they had distinctive inclusions staining for ubiquitin, a class of proteins one of whose normal functions is to mediate the selective degradation of other proteins. More recently, careful biochemical analysis has revealed that the predominant protein in these inclusions is TDP-43, an RNA binding protein (Neumann et al. 2006).

For several years, the predominant notion was that these cases must have complex mutations at the MAPT locus: however, eventually, Baker et al. (2006) identified that the locus responsible for the cases without MAPT mutations was the progranulin gene (PGRN) which is about 1 Mb
dementia. In contrast, patients with DLB first present with a profound, late-onset dementia, which was later genetically linked to chromosome 3. Eventually, a complex splicing mutation in the endosomal sorting protein, CHMP2B was identified (Skibinski et al. 2005). However, no other convincingly pathogenic mutations have been found. It currently seems most likely that this mutation is indeed pathogenic, but that its pathogenicity is dependent on the unusual nature of the mutation, which adds a nonsense sequence to the C-terminal of the protein (Momeni et al. 2006).

Lewy Body Dementia
As in the case of FTD, recent classification schemes have tried to “lump” rather than “split” disorders that are unified by having both dementia and Parkinsonism (bradykinesia, resting tremor, gait instability, rigidity) as their key clinical characteristics, and Lewy bodies in both the subcortex and neocortex as their histological characteristics. The term Lewy body dementia (LBD) is now commonly used to encompass both Parkinson’s disease with dementia (PDD) and dementia with Lewy bodies (DLB).

Clinical Features and Anatomical Profiles
A growing number of studies are suggesting that dysfunction of the posterior parietal and anterior occipital regions are the neocortical sites that best distinguish LBD from FTD and AD. This anatomical pattern has been implicated by functional imaging studies, showing hypometabolism in these regions, and neuropsychological studies that often uncover dominant dysfunction in visuospatial and visuococonstructive abilities. Furthermore, LBD patients often present with visual hallucinations as a primary and early symptom.

Both the PDD and DLB subtypes of LBD present with Parkinsonism, reflecting underlying dysfunction in the basal ganglia. The temporal profile in which neocortical and basal ganglia dysfunction emerge is a key feature distinguishing PDD and DLB. Specifically, in PDD the basal ganglia is targeted first followed by involvement of the neocortex, while in the DLB the temporal profile is reversed. Thus, patients with PDD are typically diagnosed first as having classic Parkinson’s disease that then, over time, progress to develop dementia. In contrast, patients with DLB first present with dementia that then progress to develop extrapyramidal signs and symptoms.

Because of the delayed onset of dementia, PDD does not typically present a diagnostic dilemma. The same is not true for LBD, and so when presented with a patient with a primary diagnosis of dementia, diagnostic features have been proposed that aid in distinguishing LBD from AD or FTD. In addition, patients with long-standing AD can manifest Parkinsonism as well. So, together with evidence of relatively early Parkinsonism and visual hallucinations, patients with LBD typically have fluctuating cognition, and can have rapid eye movement sleep disorders, neuroleptic hypersensitivity, and reduced dopamine transporter activity assessed by neuroimaging.

Diagnosis and Treatment
When a patient presents with dementia the clinical diagnosis of LBD is made when (a) the history of the illness suggests a slowly progressive process that begins with complaints that localize to the basal ganglia and posterior cortical sites; (b) other illness have been ruled out (i.e., blood tests to rule out B12 deficiency, hypothyroidism, and syphilis, and brain imaging to rule out large strokes, tumors, or bleeds); and (c) when neuropsychological testing suggests dominant dysfunction in posterior cortical sites, and relative preservation in hippocampal-dependent and frontal lobe-dependent tasks. Imaging studies can strengthen the diagnosis. Specifically, functional imaging studies might reveal dominant hypometabolism in the posterior cortical sites. Currently, the diagnosis of “definite” LBD can only be made when brain tissue is examined, typically showing Lewy bodies in the basal ganglia as well as in the neocortex.

Dopaminergic agents are typically effective in the extrapyramidal signs of PDD, but less so for DLB. Because of their hypersensitivity to neuroleptics, the use of this drug category for symptomatic treatment of hallucinations should be used with extreme caution.

Genetics
Because DLB is an overlap disorder, its genetics are a complicated. For example, some AD cases with APP or presenilin mutations have Lewy bodies in addition to neuritic plaques and there is an association with the APOE4 allele as there is with AD. However, individuals with α-synuclein mutations can have a pure DLB (without plaques). However, this situation is most easily reconciled with the view that α-synuclein aggregation is the proximal reason for cell death in these diseases and this can be caused directly through α-synuclein mutations or overexpression, but that this process is potentiated by Aβ.

Prion Diseases
Prion diseases are neurodegenerative disorders caused by the transmissible particles that contain a pathogenic isoform of the prior protein. The most common prionopathy is Creutzfeldt-Jakob disease (CJD), which is further subdivided based on modes of transmission: (a) sporadic CJD, whose etiologic basis remains unknown (thus “sporadic”); (b) familial CJD is an inherited form that follows an autosomal-dominant pattern of transmission; (c) iatrogenic CJD, which is typically caused in patients who received contaminated corneal transplants or injections of hormones.
extracted from human pituitary glands, and in surgeons who are exposed to contaminated surgical instruments; and (d) variant CJD, which was first described in 1994, occurring in patients who have consumed cattle contaminated with bovine spongiform encephalopathy.

**Clinical Features and Anatomical Profiles**
Anatomically, CJD targets subcortical structures including the basal ganglia and thalamus, as well as widespread involvement of the neocortical mantle, in particular the frontal lobes and posterior cortical sites including the occipital lobes, and the cerebellum. This accounts for the wide range of symptoms found in patients with CJD, including change in sleep, cognitive deficits, visual disturbance, and gait instability. Sporadic CJD, by far the most common form, typically presents after the fifth decade of life. Variant CJD is found in younger patients, and has the additional distinguishing feature of presenting with painful sensory symptoms and more florid psychiatric manifestations.

**Diagnosis and Treatment**
Clinically, CJD is typically dissociated from other neurodegenerative processes by the rapidity of its progression (thus, it is often called a subacute, not achronic, encephalopathy), by the evidence of cortical, basal ganglionic, and cerebellar dysfunction, and by the appearance of stimulus-induced myoclonus. Ancillary tests include EEG, which can sometimes show characteristic abnormal biphasic and triphasic complexes; MRI which can sometimes show increased signal intensity in the basal ganglia; and CSF studies, with elevated levels of the 14-3-3 protein found in most cases. There is currently no treatment for this devastating disease, which typically kills patients within a couple of years of diagnosis.

**Pathological Features and Pathogenesis**
Prion diseases, historically, were called the spongiform encephalopathies because of the characteristic spongy appearance of the pathological tissue. The histopathology can be very variable, from clearly defined plaques of the prion protein to very subtle deposition. The distribution of the deposition is also very variable, with the entire cortex and basal ganglia as well as cerebellum, all capable of having deposits and evidence of spongiform change.

While the mechanism of cell death in prion diseases still remains mysterious, the basic principles of disease initiation have become clear. The prion protein is at the center of the disease process and can exist as one of two forms: the “normal” form (PrP\(^{\text{c}}\)) and the pathologic form PrP\(^{\text{Sc}}\) (Sc stands for scrapie, the prion disease of sheep) (Prusiner 1982). On interaction with PrP\(^{\text{c}}\), PrP\(^{\text{c}}\) is converted to PrP\(^{\text{Sc}}\) by a templating mechanism. As the concentration of PrP\(^{\text{Sc}}\) increases, the pace of propagation accelerates. PrP\(^{\text{Sc}}\) exists as several different variants and these correspond to the “strains” (Hill and Collinge 2001). Each of the strains (the number is unknown, but certainly of the order of a dozen) corresponds to a different structure; each has differing clinical effects and attacks different neuronal predilections. Bovine spongiform encephalopathy/new variant CJD corresponds to a new strain of PrP\(^{\text{Sc}}\) (Jackson and Collinge 2001). Part of the determinant of strain/PrP\(^{\text{Sc}}\) structure is a common coding polymorphism, M129V. New variant, CJD, for example, cannot occur in someone with a V129 allele (Wadsworth et al. 2004).

With this background, many of the bizarre features of prion disease become easier to understand. Infectious/iatrogenic CJD occurs when the origin of the PrP\(^{\text{Sc}}\) is in the contaminating material (whether it is food, or contaminated surgical instruments): hereditary prion disease occurs when there is a mutation in the prion gene, which makes a transition from PrP\(^{\text{c}}\) to PrP\(^{\text{Sc}}\) more likely and sporadic disease occurs, most plausibly, by a stochastic conversion from PrP\(^{\text{c}}\) to PrP\(^{\text{Sc}}\). In all cases, the more efficient the conversion from PrP\(^{\text{c}}\) to PrP\(^{\text{Sc}}\) the more efficient the disease process. Thus, prion gene homozygosity at codon 129 predisposes to sporadic disease and M129 homozygosity predisposes to new variant CJD (Wadsworth et al. 2004).

This simple explanation leaves many questions unanswered: the precise structural determinants and the number of strains is not clear. But perhaps most mysterious of all, is the reason that the prion gene has evolved to have such bizarre structural propagation properties is completely mysterious.

**Conclusions**
As reviewed above, the last 10 years in particular have brought a revolution in our understanding of the initiating lesions in many of the dementia: we have clear outlines of some of the initial steps in their molecular pathogeneses. In general, however, we have almost no understanding of how the genetic lesions initiate the reasonably selective neuronal losses that distinguish the diseases: neuronal selectivity is still a black box into which we cannot yet peer. Finally, and most importantly, our improved molecular understanding has not helped us at all with mechanism therapies yet. To the extent we have therapies for these devastating disorders, we rely on transmitter-based therapies. We have to hope that the next 10 years will see some improvement in this regard.

Psychological and Social Scientific Foundations of Psychiatry
Overview
The President’s New Freedom Commission in the United States and the Green Paper from the European Union have outlined key goals for reducing the burdens from mental disorders (President’s New Freedom Commission on Mental Health 2003, Health and Consumer Protection Directorate General 2005). These have included increasing public awareness of the frequency and consequences of mental disorders, understanding and reducing stigma and disparities in mental health, as well as promoting early detection and timely receipt of high-quality treatment. Accomplishing all of these important goals will clearly rely heavily on contributions from the field of psychiatric epidemiology.

The discipline of psychiatric epidemiology is at its most basic level the study of the patterns of mental disorders, including how frequently disorders occur, how they are distributed in populations, and what are the associated risk factors. Psychiatric epidemiology also defines the time course of mental disorders including their onset, duration, and recurrence. This basic information is fundamental to the understanding of mental disorders and the development of effective intervention and prevention programs. Recently, the field has greatly expanded and now includes detailed examinations of the natural history of psychiatric disorders, genetic epidemiology, the relationships between physical and mental disorders, and studies of the use and outcomes of mental health treatments. This expansion has required significant advances and developments in psychiatric epidemiologic methods (Tsuang and Tohen 2002). This progress has also benefited from the continuing operation of doctoral and postdoctoral psychiatric epidemiology training programs in centers throughout the United States funded by the National Institute of Mental Health (NIMH).

Important characteristics that distinguish psychiatric epidemiological research from other clinical investigations are the inclusion of representative samples and the application of systematic methods for determining diagnosis or outcome. The specific type of sample and choice of mental health measure depend on the goal of the study. For studies aimed at establishing prevalence and incidence rates, the population-based survey is the optimal method. Complex sampling procedures have been developed to ensure random selection for both single-stage- and two-stage studies. For rare disorders, identified patients are usually ascertained from registries or a representative set of psychiatric treatment facilities. However, because only a minority of individuals with diagnosable disorders are ever treated for psychiatric problems within the mental health care system (Regier et al. 1993, Kessler et al. 1994, Wang et al. 2000), these sources may omit true case patients who do not present for treatment. Another source for epidemiological samples is an institution, such as a psychiatric hospital, general medical facility, school, or workplace. There has been particular interest recently in conducting psychiatric epidemiologic research in primary medical care settings, both because individuals with psychiatric disorders are relatively heavy utilizers of general medical services and because primary care providers are increasingly being given the responsibility of treating mental disorders (Schulberg 1991, Von Korff et al. 1992). Such studies have focused on the recognition and treatment of mental disorders and the specific patterns of health service use by patients with diagnosable psychiatric conditions (Wells et al. 1994, Coyne et al. 1995). In the past, defining “caseness” in psychiatric epidemiologic studies has been difficult. The lack of reliable and cost-efficient methods for making diagnoses has been a central impediment to conducting research that could yield even basic data on the occurrence of mental disorders. Earlier studies have employed case definitions ranging from scoring above a threshold on a general symptom inventory to...
receiving mental health services. The development of structured diagnostic interview schedules (DISs) tailored to clear, operationalized diagnostic criteria was the crucial element underlying the recent progress in psychiatric epidemiology. As a result of the development of structured DISs, the need to establish the prevalence of specific disorders was finally realized, at least within the limits of our current ability to operationalize mental disorders and within the constraints inherent in interview data (Fennig and Bromet 1992). Estimates suggest that approximately 12% of children (Institute of Medicine 1989) and 15% of adults (Regier et al. 1988) currently meet criteria for one or more mental disorders. More precise estimates will be possible as more sensitive diagnostic tools become available.

This chapter begins with a description of the scope of questions covered in psychiatric epidemiologic investigations. We then briefly cover the methodology that characterizes psychiatric epidemiological research, focusing on the strengths and limitations of different approaches particularly with respect to reliability and validity. This is followed by a discussion of examples of important psychiatric epidemiologic studies, including their findings and critical developments that made them possible. Finally, we conclude with a brief discussion of continued challenges to conducting psychiatric epidemiological research and the need for future developments.

**The Scope of Inquiry in Psychiatric Epidemiology**

“Epidemiology” is derived from the Greek words *epidemos*, meaning “among the people,” and is defined as the study of “the patterns of disease occurrence in human populations and of the factors that influence these patterns” (MacMahon and Pugh 1970). Because the ultimate goal of epidemiological research is to understand the cause of disease and prevent its occurrence, epidemiology is the backbone of public health. Among the earliest epidemiologic investigations is that of John Graunt (1939), who in 1662 used birth and mortality records collected by parish clerks to study variations in birth and death patterns by sex, urban-rural residence, and seasonality, in hopes that such data could provide clues toward understanding human disease. Early epidemiologic research also includes the work of John Snow (Snow 1856). Snow concluded that the London cholera outbreak of 1848 was associated with the discharge of fecal waste into the water supply, after observing that the mortality rate among residents served by a company whose source was from a heavily polluted part of the Thames River was eight to nine times higher than that of residents served by the other company whose water was drawn from a less contaminated part of the river. Importantly, Snow reduced the level of mortality by turning off the offending company’s pump, thus demonstrating that prevention efforts can be highly successful even if the specific cause of a disease (in this case, a microorganism) is not known. The principles by which modern epidemiologic studies are now conducted, have largely emerged since the end of World War II (Rothman and Greenland 1998). With the establishment of such principles, large-scale epidemiologic studies on numerous diseases and conditions have proliferated. Results of these studies have had a profound impact on our understanding of diseases (e.g., cardiovascular disease), their risk factors (e.g., smoking), and on public health (e.g., highly successful primary prevention programs for infectious diseases such as poliomyelitis).

Important advances have also been made in psychiatric epidemiology, largely since World War II. To make such advances, investigators have had to overcome formidable problems that are fairly unique to the study of psychiatric disorders. Foremost among their achievements has been the development of the ability to define mental disorders reliably and efficiently. This accomplishment has, in turn, allowed investigators to conduct descriptive analyses that have yielded much-needed estimates of the incidence, prevalence, age at onset, and frequency of recurrence of mental disorders.

The ability to accurately categorize cases and noncases has also been essential for allowing psychiatric epidemiologists to progress from simple descriptive work establishing rates, to analytical research aimed at identifying risk factors as well as biological and psychosocial variables that modify the effects of these risk factors. Examples of promising areas in which there has been significant research activity include investigations of the genetic bases for psychiatric disorders (Risch and Merikangas 1996) and the modification of risk by environmental exposures, especially in the prenatal period (Neugebauer et al. 1999). Whereas traditional epidemiology has largely been concerned with the occurrence and causes of disease, clinical epidemiology has emerged as a closely related discipline which seeks to identify the occurrence and determinants of clinical outcomes from illnesses (Sackett et al. 1985, Weiss 1985). Clinical epidemiologic studies employ the same principles and methods of population-based epidemiology, but are usually conducted among clinical samples. Clinical epidemiologic investigations, such as the NIMH Collaborative Program on the Psychobiology of Depression (CPPD) and the Harvard–Brown Anxiety Research Program have provided important information on prognostic factors associated with the natural history of psychiatric disorders (Judd et al. 1998, Rogers et al. 1999). Other examples include two countywide longitudinal studies of first-admission psychosis (Beiser et al. 1989, Bromet et al. 1992), which included patients from all facilities in the respective geographical regions, a follow-up study of first-episode psychotic patients admitted to the McLean Hospital in Belmont, Massachusetts (Tohen et al. 1992), and the Avon Longitudinal Study of Parents and Children [ALSPAC], a prospective cohort study following 14,000 children and their mothers (Golding et al. 2001).

Psychopharmacoepidemiology has been an especially fast growing component of clinical epidemiologic inquiry (Wang et al. 2003), in part because psychotropic medications are now widely used in both general medical and psychiatric populations. Many psychopharmacoepidemiologic studies have consisted of descriptions of the patterns and predictors of psychiatric medication use (Wang et al. 2000, Olsson et al. 2002) as well as investigations of unanticipated hazards from psychiatric medications (Wang et al. 2001a, 2001b, 2001c, Wang et al. 2002a, 2002b).

Clinical epidemiologic research has also begun to evaluate the economic costs associated with mental disorders, both the direct costs for provision of mental health services as well as the indirect costs to society secondary to the disability caused by disorders. The WHO Global Burden of
Disease (GBD) study (Murray and Lopez 1996) identified mental disorders as among the most costly diseases in the world. For example, major depression was the single most burdensome disease in the world among individuals under 45 years of age. Another closely related area of inquiry is that of mental health services research. This discipline investigates the patterns of utilization of mental health services, unmet needs for treatment, barriers to help-seeking, the appropriateness and quality of treatments, and premature dropout from treatment (Wang et al. 2000, 2002, Kessler et al. 2001a, Edlund et al. 2002).

The accumulation of information on risk factors for mental disorders, their outcomes, and treatment has, in turn, led to another important line of inquiry in psychiatric epidemiology, namely, interventional research. In addition to efficacy trials of psychiatric treatments conducted under rigorously controlled conditions (Tohen et al. 2000, 2002), experimental studies have also begun to include effectiveness trials of “real-world” treatment strategies (Katon et al. 1995, 1996, Simon et al. 2000, Wells et al. 2000). Finally, the proliferation of effective but costly interventions, coupled with growing constraints on health care budgets, have also made it imperative to study not only the effectiveness of interventions but also their cost-effectiveness and cost-benefits. For this reason, economic analyses now frequently accompany efficacy and effectiveness trials of interventions (Schoenbaum et al. 2001).

**Epidemiological Methods**

Conducting investigations across this broad scope of inquiry has required the development of rigorous psychiatric epidemiologic methods. The following section contains a brief description of some of the basic elements of this methodology.

**Measures of Disease Frequency**

Epidemiological studies examine the incidence and prevalence rates of disorders in populations at risk and the factors associated with onset and recurrence. A rate is determined by the number of cases (the numerator) divided by the population at risk (the denominator).

**Incidence**

Incidence rates refer to new cases that arise in a healthy population during a fixed time. The most commonly applied incidence rate in psychiatric epidemiology is the cumulative incidence rate, also known as the incidence proportion (Selvin 1991), that is, the proportion of a population at risk that has a disease during a specified time. For example, we wished to determine the cumulative incidence rate of depressive and anxiety disorders in a sample of mothers of young children during the year after the accident at the Three Mile Island nuclear power plant. A total of 312 women with small children living within 10 miles of the plant were interviewed with the SADS-L (Bromet et al. 1982). Of them, 84 met research diagnostic criteria for major depression or generalized anxiety disorder before the accident. Forty-five cases occurred during the year after the accident, of which 26 were first-onset or incident cases. The 1-year cumulative incidence rate is, thus, 26 divided by 228 (the total sample less those with a prior history, or 312–84), or 11.4%.

Cumulative incidence is appropriate when a study has a fixed cohort design (i.e., when all of the members of the cohort are observed for the same time). However, when attrition occurs, the cumulative incidence rate is a less desirable measure. Individuals lost to follow-up who would have become case patients are excluded from the numerator, whereas the denominator, which is the total population, remains unchanged. Moreover, those who become lost to follow-up are often a biased subgroup of the original study population (Eaton et al. 1992). Therefore, cumulative incidence should be considered most reliable when there is a small loss to follow-up during the specified time. When loss to follow-up occurs or when the occurrence of a health outcome is measured in a dynamic cohort (i.e., when members of the cohort come in and out, different statistical adjustments must be employed) (Selvin 1991).

Cumulative incidence = \( \frac{\text{number of new cases}}{\text{total population at risk}} \)

In epidemiology, incidence rate refers to the number of new cases occurring in a specified time period divided by the sum of time periods of the observation for all individuals in the population at risk, or person-time (Rothen and Greenfield 1998). For example, suppose an investigator wishes to calculate the incidence rate of suicide in 100 patients with mania during the 5-year period after initial diagnosis. The numerator is the number of patients who committed suicide, and the denominator is 100 patients × 5 years, or 500 person-years. If five suicides occur, the incidence rate of suicide will be 5 divided by 500 person-years. The units of incidence rates are time⁻¹. Because the units and the numerical value of an incidence rate are difficult to interpret, incidence rates are usually compared with each other to obtain incidence rate ratios.

Incidence rate = \( \frac{\text{number of new cases}}{\text{person-years}} \)

**Prevalence**

Prevalence rates measure the proportion of individuals who have the disease at a specified point or period in time. Incidence refers only to new-onset cases, whereas prevalence includes all new, recurrent, or chronic cases in the numerator and the entire population, including those with a history of the disorder, in the denominator. The point prevalence rate is the proportion of a population affected by a disease at a given point in time. Period prevalence refers to the proportion of a population affected by a disease during a specified time period, such as 6 months, 1 year, or lifetime. Prevalence rates are influenced by the duration of a disease. For nonchronic disorders, such as major depression, the point prevalence is usually lower than the period prevalence. For chronic conditions, such as schizophrenia, the point prevalence and period prevalence are expected to be similar.

Prevalence rate = \( \frac{\text{number of cases}}{\text{total population at risk}} \)

In general, prevalence data are less useful than incidence data for etiological research. Prevalence is determined not just by factors that cause a disease but by factors secondary to the disease itself. On the other hand, prevalence measures
are useful in public health or service utilization situations. For instance, the geographical location and planning of specific services of a community mental health center are usually based on findings from prevalence studies.

**Measures of Association**

Incidence rates can be used to calculate two types of effects. One is the attributable risk, or the absolute effect. The attributable risk is the difference between two incidence rates. This is most commonly used in comparing rates of exposed with nonexposed populations. For example, the Three Mile Island study included a sample of mothers of young children living near another nuclear power plant in Pennsylvania. The risk of depression and anxiety attributable to the Three Mile Island accident was the incidence rate in the exposed population (11.4%) minus that in the comparison population (3.2%), or 8.2%. The second type of effect is the relative risk, which is the ratio of the incidence rates of the exposed and unexposed groups. In the same example, the relative risk was 3.56%. In case-control studies, it is not possible to estimate incidence rates. Relative risks, however, can be calculated with an odds ratio, which is the ratio of the odds of exposure of the case patients to that of the control subjects (Figure 25–1).

**Instruments to Identify Cases**

The lack of reliable and cost-efficient methods for making diagnoses has been a central impediment to conducting research that could yield even basic data on the occurrence of mental disorders. Earlier studies have employed case definitions ranging from scoring above a threshold on a general symptom inventory to receiving mental health services. The development of structured DISs tailored to clear, operationalized diagnostic criteria has been the crucial element underlying the recent progress in psychiatric epidemiology.

The history of development of uniform methods for eliciting and quantifying clinical information largely starts with the United States–United Kingdom project (Cooper et al. 1972), in which previously observed cross-national differences in the distributions of schizophrenia and affective disorders in hospitalized patients disappeared when consistent diagnostic procedures were administered. The feasibility and benefits of structured, or semistructured, interview schedules that could systematically elicit criteria for objectively defined disorders further became evident after the appearance and widespread use of instruments such as the Schedule for Affective Disorders and Schizophrenia (SADS) (Endicott and Spitzer 1978), the companion interview for the Research Diagnostic Criteria (Spitzer et al. 1978). The SADS and the Research Diagnostic Criteria were originally developed for use by psychiatrists in the multisite Collaborative Study of the Psychobiology of Depression sponsored by the NIMH (Katz et al. 1979). Two community-based studies demonstrated that master’s-level mental health professionals could successfully administer the lifetime version of the SADS (SADS-L) for epidemiological purposes (Weissman et al. 1978, Bromet et al. 1982). Other standardized psychiatric interviews that have been commonly used are the Present State Examination (Wing et al. 1974) and its successor, the Schedule for Clinical Assessment in Neuropsychiatry (Wing et al. 1990); the Structured Clinical Interview for DSM-III-R (Spitzer et al. 1992); and the Diagnostic Interview for Genetic Studies developed by the NIMH-sponsored centers for genetic linkage research (Nurnberger et al. 1994). Puig-Antich et al. have also developed an instrument for use with children, the Kiddie-SADS, that has been modified for epidemiological studies (Orvaschel 1985).

Robins (Robins 1978) was among the first to advocate the development of fully structured DISs that could be administered in the community by non–mental health professionals or lay interviewers. Although some such instruments were developed before the introduction of the Diagnostic and Statistical Manual of Mental Disorders, Third Edition (DSM-III), the first widely used of this family of instruments is the DIS (Robins et al. 1981). The DIS was originally designed for the five-site Epidemiological Catchment Area (ECA) study of DSM-III disorders (Regier et al. 1984). Subsequent versions of the DIS incorporated revised DSM-III (DSM-III-R) as well as Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV-TR) criteria. In the field of children’s mental health, fully structured DISs have also been designed, such as the DIS for Children (Costello et al. 1988, Jensen et al. 1995).

Another fully structured instrument is the Composite International Diagnostic Interview (CIDI), developed in collaboration with the World Health Organization (World Health Organization 1990) and NIMH (Wittchen et al. 1991). The CIDI was designed to be used with both DSM and International Classification of Diseases (ICD) diagnostic criteria and to be available in multiple languages. Since it first became available in 1990, the CIDI has been used in the National Comorbidity Survey (NCS) (Kessler et al. 1994), the National Comorbidity Survey Replication (NCS-R), as well as other major epidemiologic surveys in many countries (Wittchen et al. 1992, Bijl et al. 1998, Caraveo et al. 1998). The WHO created the International Consortium in Psychiatric Epidemiology (ICPE) in 1997, in part, to oversee and facilitate comparative analyses from such international surveys employing the CIDI (Kessler 1999). The currently ongoing WHO World Mental Health Survey (WMH) initiative, which involves surveys of the general population in over 30 countries throughout the world, also employs the CIDI (Kessler 2000).

**Psychometric Properties of Instruments**

An instrument’s sensitivity (proportion of those with true-positive results identified as such by the study instrument) and specificity (proportion of those with true-negative results identified as such by the study instrument) are one set of measures. For an instrument to be useful in epidemiology, it should have high sensitivity and, at least, moderately high specificity.
To identify cases accurately, an instrument used for case identification must be reliable and valid. Reliability refers to the reproducibility of a measure (i.e., the consistency of measurement regardless of the rater, the situation, or the time of administration). Interrater agreement is usually calculated with statistical methods, such as the kappa statistic, which control for chance agreement. Test-retest reliability, or temporal stability, is calculated with product-moment or intraclass correlation coefficients. Validity refers to whether a construct is measured accurately. This concept is more difficult to establish in psychiatry because there is generally no “gold standard” or biological marker for the disorders under study.

A number of studies assessing the reliability of the DIS have found it to vary depending on the diagnosis under consideration and to be better when the DIS is compared with itself in the hands of a physician (Helzer et al. 1985) than when it is compared with other semistructured diagnostic instruments (Anthony et al. 1985). Clinical reappraisal studies have documented acceptable to good concordance between most CIDI diagnoses and blind clinical reinterviews using the Structured Clinical Interview for DSM-IV-TR (SCID) as the validation standard (Spitzer et al. 1987, Kessler et al. 1998). Exceptions include mania (Kessler et al. 1997) and nonaffective psychosis (Kessler et al. 1996), both of which are overdiagnosed by the CIDI according to clinical reinterviews. Overdiagnosis of mania has been handled in the NCS by confining received CIDI diagnoses to the euphoric-grandiose subtype of mania, which was assessed with good validity. Overdiagnosis of nonaffective psychosis was addressed in the NCS by carrying out clinical reinterviews with all respondents who screened positive for nonaffective psychosis by the CIDI and basing final diagnoses on these clinical assessments rather than on the original CIDI classifications.

**Risk Factor Identification**

Risk factors are characteristics whose presence increases the chances for development of a disease. A true risk factor must exist before a disease develops. For example, being male and having a family history of alcoholism are risk factors for the development of alcoholism (Merikangas 1990). When a variable cannot be definitively proved to predate the onset of a disorder, it is best conceptualized as a correlate. For example, although socioenvironmental factors, such as adverse life events and chronic strain, are statistically associated with the development of depressive disorders, they usually should be regarded as correlates because the causal sequence of these relationships is difficult to determine.

Psychiatric epidemiologists are increasingly turning their attention to the identification of modifiable risk factors for psychiatric illnesses. A major goal of such work is to shed light on information that can guide the development of successful interventions for primary and secondary prevention efforts.

**Types of Epidemiological Studies**

In general, epidemiological studies are designed to find associations between exposures and health outcomes. A main concern in epidemiological studies is the selection of study groups on the basis of either disease status or exposure status. Epidemiological studies can be classified as (1) experimental, (2) quasi-experimental, and (3) nonexperimental or observational.

**Experimental Studies**

The main distinction of experimental studies is that the investigator assigns the status of exposure or nonexposure to each subject. The assignment to the exposure group becomes part of the study protocol. Once subjects are assigned to exposed or nonexposed groups, they are observed for a time, and observations about changes in morbidity are recorded. The most common experimental design is the clinical trial, in which clinical populations are exposed to a specific treatment protocol to measure an outcome, usually resolution of symptoms. To ensure the integrity of a clinical trial, three main elements are necessary (Miettinen 1985): (1) randomization, to ensure comparability of the populations; (2) placebo, to ensure comparability of the effects; and (3) “blinding,” to ensure comparability of information.

In randomization, subjects are randomly assigned (e.g., through a random number generator) to different exposure groups to attempt to ensure that subjects in each group have similar clinical and demographic characteristics. It is possible that with a small sample size, the groups may have different characteristics in spite of randomized allocation. If these characteristics are factors that could affect the outcome, they then need to be controlled for in subsequent analyses. Of course, in many cases, not all factors predicting a good or a poor outcome are known. Randomization should theoretically achieve a balance of unknown factors in the different groups.

Placebo groups are used to ensure that extraneous effects of a specified experimental treatment (such as extra attention from an examiner) do not alter or account for the experimental findings. A placebo controls for factors that may affect the outcome of the study independently of the exposure status. For example, if subjects in an open trial are aware of what medication they receive, this knowledge could bias their response to the treatment. Similarly, subjects who are aware of being in an untreated control group could respond over time in a biased fashion as a result of this knowledge. One goal in assigning patients at random to treatment or placebo control groups is to keep the subjects from being aware of whether or not they are receiving treatment. In a single-blind study, only the patient is unaware of the actual treatment. In a double-blind study, the investigator and the subject of investigation are unaware of treatment assignment. In a triple-blind study, the data analyst is also not informed of the meaning of the group assignment code.

**Quasi-Experimental Studies**

Natural experiments that permit comparisons of two populations, one that receives an exposure and the other that does not, are referred to as quasi-experimental studies. Even though the investigator does not have full control over the exposures and environments, these designs still permit an understanding of the influence of different environmental constraints.

To be considered quasi-experimental, baseline data must have been collected before the exposure event. Without that requirement, the study is simply a retrospective observational study. For example, during the course of the
Three Mile Island investigation, widespread unemployment occurred at the Pennsylvania comparison site because of massive layoffs from a recession in the steel industry. Since data for the original Three Mile Island project had already been collected at the comparison site, Penkower et al. (Penkower et al. 1988) were able to chart the long-term effects of husbands’ layoff and to identify prior-event predictors from interview data obtained before the layoffs occurred.

Nonexperimental Studies
Nonexperimental studies are divided into cross-sectional and longitudinal designs.

Cross-Sectional Designs
Cross-sectional designs are typically employed in surveys aimed at providing data on the distribution of disorders in the population. Differences in rates by basic demographic data are also usually derived. In epidemiology, cross-sectional designs are usually best employed when causal hypotheses are not being tested. For example, when a community wants to investigate the distribution of an illness to decide on the need for psychiatric services, a cross-sectional survey is highly appropriate. Even though cross-sectional data may be limited in terms of the level of inference that can be drawn, such surveys must still assess a well-defined population at risk with reliable assessment tools to be epidemiologically useful. For example, surveys that are based on volunteers or instruments with no established psychometric utility are not regarded as using epidemiological methodology.

Cross-sectional studies include not only current symptoms but also retrospective data on age at onset of the disorder. With sophisticated statistical modeling techniques, it is possible to develop informed hypotheses about links between potential risk factors and disease. However, the true test of such hypotheses must be drawn from data obtained prospectively.

Longitudinal Designs
Longitudinal designs are divided into case-control and cohort studies and are characterized by a time interval between cause and effect. In cross-sectional studies, there is no interval between exposure and illness, which are measured at the same point in time.

Case-Control Studies
In case-control studies, subjects are defined in terms of having (case patients) or not having (control patients) the disease of interest. The groups are compared in terms of history of exposure. In general, two types of control groups are used: hospital control groups and population control groups. The selection of the control group is a key point in terms of validity. Control subjects should be selected independently of exposure status. Case and control patients may be matched on different characteristics, the key issue being that control patients should represent those individuals who, if they had the disease, would be selected as case patients (Miettinen 1985). One of the most widely cited case-control studies focused on the role of stressful life events in the onset of depression (Paykel et al. 1969). In this study, women treated for depression were assessed about their previous life events, and a control group of non-depressed women were similarly assessed. Calculations were then made of the excess risk of depression associated with the occurrence of life events.

Among the strengths of case-control studies are their feasibility and relatively low cost. Case-control studies allow the evaluation of multiple hypotheses and are the ideal design for investigating rare diseases, such as anorexia nervosa. The primary limitation of case-control studies is potential recall bias, particularly in the control patients for whom there may be no corroborating record information. In addition, it is often difficult to obtain suitable data on rare exposures.

Case-control studies can assess whether a risk factor is more prevalent in case than in control patients but may not be able to establish the rate of disease after exposure to that risk factor. For the purpose of estimating the true rate of disease associated with an exposure, the prospective cohort study design is the preferable methodology.

Cohort Studies
